"A considerable amount of waste, partly from the stripping mixed with the surface rock and partly from seams, comes down in the quarry. The rock is cleaned of muck as it is loaded with forks into cars at the working face, and the accumulated muck is removed with Fresno scrapers between shifts. The cars used in the quarry are 36-in gage end dumping quarry cars having a capacity of from 2 to 2½ tons and a total height of 30 in. They are snatched by mules to the main quarry line and there, in trains of 10 cars, drawn by a 5-ton electric locomotive a maximum distance of 400 ft over a trestle to the tipple above the crusher. They are dumped by means of a special automatic cross-over mine tipple and returned to the quarry by a gravity switchback. Ten cars can be dumped in 4 min, and only one man is required to operate the mechanism.

"The rock is fed into a No. 6 gyratory crusher by one man. From this crusher it passes thru a preliminary 8-in screen, the rejections from which are returned and crushed in a No. 4 gyratory crusher. The total product is then transported by a belt conveyor to final sizing screens over the storage bins. These screens separate the stone into 4 sizes which are stored in the bins for gravity loading into railroad cars."

Quarry and Plant at Newton, Mass. (35a). The crusher was placed near a ledge of hard, green trap rock. The stone was drilled with a Rand steam drill and broken to size to go into the crusher by sledge hammers, and taken by horses and carts to the crusher, a distance of about 500 ft, and delivered on a platform level with the top of the hopper. It was fed into the hopper by two laborers. Unit costs were as follows, wages being for a 9-hr day: Foreman, $3; operator, steam drill and boiler, $3; operator crusher, $2; blacksmith, $2.50; laborer, $1.75; two one-horse carts and drivers, $5; powder per 50-lb box, $11.34; coal per ton, $5.90; oil per gal, $0.15; waste per lb. $0.09.

	Cost per Cu Yd	Cost per Ton
Labor, steam drilling	$0.092	$0.076
Steam drilling, including coal, oil, waste, powder, repairs	0.084	0.070
Sharpening drills and tools	0.069	0.058
Breaking stone for crusher	0.279	0.231
Loading stone for crusher	0.098	0.081
Teaming stone for crusher	0.072	0.060
Feeding stone to crusher	0.053	0.044
Engineer of crusher	0.031	0.026
Coal, oil waste and repairs of crusher	0.079	0.065
Repairs	0.041	0.034
Total	$0.898	$0.745

Tompkins Cove Crushing Plant, Rockland County, N. Y. (17). "The rock is blasted from a high vertical quarry face, loaded by steam shovels to cars on a high level track, and drawn an average distance of about 800 ft to the top of the crusher house. It is dumped directly into the crusher hopper and passes vertically downward thru three successive sets of horizontal crusher rolls, which reduce it to a maximum size of about 2 in. From the lower rolls it is raised about 90 ft by a steeply inclined steel pan elevator which discharges into a hopper in the top of the preliminary screen house. This hopper discharges into a distributer that spreads the broken rock evenly over a gravity screen that removes all stone larger than 1½ in and delivers it to a belt conveyor by which it is returned to the last pair of rolls. About 90% of the product which passes thru the preliminary screen is delivered by a belt conveyor 362 ft long, inclined about 10°, to the top of the main screen house where it passes by gravity vertically thru a stationary distributing and screening apparatus which separates it into 1½-in, ¾-in and ⅜-in sizes, each of which is discharged on a separate horizontal belt conveyor and dumped into one of the five storage bins with a combined capacity of 20 000 cu yd."

CONSTRUCTION

9. Methods of Construction

Subgrade. The subgrade is usually a shallow trench composed of two or more planes or a curved surface sloping from the center to the sides. The surface of the subgrade is generally parallel to the finished surface of the broken stone road, altho this is not true when the depth of stone at the edge of the shoulder is made less than at the center (see Figs. 5 and 6.) The subgrade has the same width as the broken stone surface. The sides of the trench, which serve to hold the stone in place, are formed by earth shoulders, generally from 3 to 5 ft in width. In places where the edge of the stone is bounded by a curb or gutter, the earth shoulder is generally omitted unless the roadway is extremely wide and only a part of the width is built of broken stone. The subgrade should be brought to true line and grade and be thoroly compacted with a steam roller. Any low spots which appear during compaction should be brought up to grade with good material and rerolled.

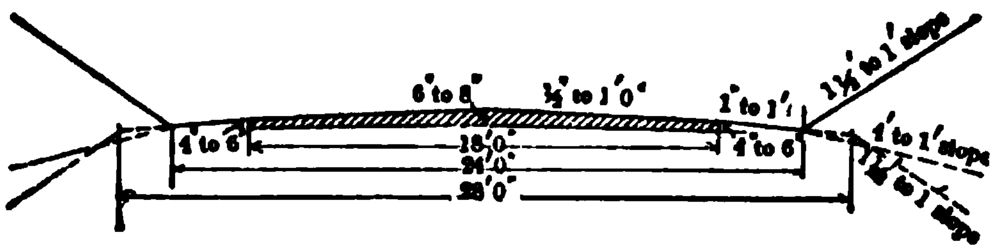

Fig. 5. Cross-Section of a Broken Stone Road on a Natural Road-Bed. Full lines show shoulders and slopes in cuts; broken lines, shoulders and slopes for embankments

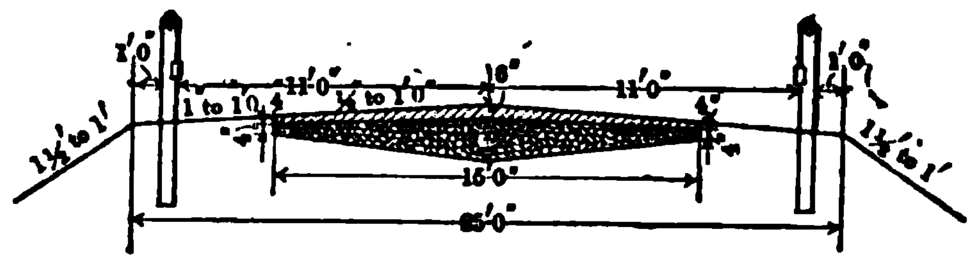

Fig. 6. Cross-Section of Broken Stone Road on a V-Drain Foundation Constructed on an Embankment

Hauling the Broken Stone. The road metal may be hauled to the highway with ordinary carts or wagons. Patent bottom dump-wagons with doors hinged on the sides or on the ends of the wagons are commonly used and serve the purpose in an excellent manner. It is possible with this type of wagon to regulate the size of opening between the bottom doors so that any width of opening up to the maximum can be obtained. By this means it is possible to spread the stone in layers as the wagon is drawn along the road. Similar wagons are built to be hauled by a traction engine. Wagons of this type generally have a capacity of 3 to 4 cu yd and are drawn in trains.

The Effect of Distance Hauled Upon the Settlement of Crushed Limestone in Wagons and Carts is given in the following table (14):

Size of Stone	Settlement After a Haul of	
	½ Mile or More in Wagons	75 Miles or More in Cars
⅛-in screenings	12.7%	......
¼-in screenings	11.8%	10.6%
2 to ¾-in	9.2%	......
3 to 2-in	8.2%	7.0%

Laying the Broken Stone. In some cases where the stone is not of a particularly good quality, better results may be obtained by placing the smaller stone in the bottom of the road and the larger sized stone on top. There are also cases where the run of the crusher from the coarse sizes down to dust is placed on the road as one course, but this method is not recommended. If the stone is brought in patent bottom dump-wagons, it may be dumped directly upon the subgrade and spread with forks. Stone brought to the work for the upper courses of a road, however, should be dumped on boards and shovelled in place to prevent the segregation of the sizes, which might occur if the stone was dumped directly upon the road from the wagons.

Thickness of Courses. All broken stone roads should be constructed in layers, each layer being rolled before a subsequent layer is placed. The thickness of any layer should not exceed 4 in after rolling, as it is impracticable to properly roll a layer of greater thickness. For roads under light traffic, assuming a good natural or artificial foundation, the total thickness of the crust, if of trap or other hard rock, need not be more than 4 in; if of softer stone, 5 to 6 in. If the traffic is heavy the thickness should be greater. A thickness of 8 to 10 in is not unusual where the traffic is of heavily loaded vehicles, that is, frequent loads of 10 tons or more. With very frequent loads of 10 tons or more, a water-bound broken stone road should not be constructed and the same is true if more than about one third of the traffic is of fast moving motor-driven vehicles. The thickness of the bottom course is varied according to the kind of foundation and the nature of the traffic to be carried. If the natural subsoil is of good firm material like good road gravel, or if the road is built upon an artificial foundation of stone, the lower course may be as thin as 2 in, provided the traffic over the roadway is of vehicles weighing not more than 4 or 5 tons. If, however, the vehicles passing over the roadway are of heavy type, the road will be sufficiently more permanent to warrant making the lower course more than 4 in in thickness. On streets of cities it is often economical to construct the lower course 6 in in thickness after rolling.

Regulating the Thickness. To gage the thickness of a layer of stone, wooden cubes made equal to the depth of a layer are sometimes placed at intervals across the roadway, the cubes being taken up and moved along as the work progresses. With this method, however, if there are any irregularities in the subgrade or in the foundation course, they will be carried up to the finished surface. A better method of regulating the depths of the different layers is to set strings longitudinally at the proper elevation at the sides and center of the roadway. In this manner the elevations are always tied in with the finished grade and any irregularities can more readily be corrected as they occur.

The Amount of Broken Stone per Unit of Area of Roadway Surface will of course vary with the thickness of the crust, but, in some cases, does not vary in exact proportions to the thickness of the crust on account of the fact that the voids in the lower courses are not always filled with stone dust. In some cases the voids are filled with dust to a depth below the top of the wearing surface of not exceeding 3 in, and often not exceeding 2 in, hence the weight per unit area of the top course is greater than the weight per unit area of the lower course or courses of the same thickness.

" Surface Covered by Various Sized Loads of Broken Stone (44). The following tabulation shows the number of linear feet of 9-ft road a load of a given size should cover for various loose depths:

Weight of Load			Loose Depth in Inches			
Granite	Limestone	Size of Load Cu Yd	3 in Ft	4 in Ft	5 in Ft	6 in Ft
2800	2500	1	12	9.00	7.2	6.0
3500	3125	1¼	15	11.25	9.0	7.5
4200	3750	1½	18	13.50	10.8	9.0
4900	4375	1¾	21	15.75	12.6	10.5
5600	5000	2	24	18.00	14.4	12.0
6300	5625	2¼	27	20.25	16.2	13.5
7000	6250	2½	30	22.50	18.0	15.0
7700	6875	2¾	33	24.75	19.8	16.5
8400	7500	3	36	27.00	21.6	18.0

Rolling. Horse-drawn rollers are not sufficiently heavy to properly roll broken stone. If the stone is a hard trap, a roller weighing from 12 to 20 tons is desirable, but if the stone is soft a roller weighing from 10 to 15 tons is better than the heavier type. Ordinarily, about 10 tons per hour is considered the amount of stone that can be properly rolled with one roller. Up to the present time steam is the only power universally successful for rollers, but gasoline engines may prove to be of use if properly designed for the variable conditions a roller is required to meet. The amount of rolling necessary depends on the character of the stone, the weight of the roller, and upon the amount of water and binder used. Trap rock requires two or three times as much rolling as most stone. The usual speed of steam rollers is 2 to 2½ miles per hr. The amount of rolling required varies from 4 to 10 tons of broken stone per hr.

Settlement in Rolling (3). In order to know the depth of loose broken stone to be spread to give a required depth after rolling, it is necessary to know the settlement due to rolling. The apparent settlement depends upon the nature of the subgrade, that is, upon the amount of stone forced into the earth. The maximum actual settlement is probably less than 20%. In the case of a subgrade so hard that wagons hauling stone made no ruts, 5¾ in of trap rock 1½ to 2¼ in in diameter, rolled with a 12-ton steam roller down to 4 in, and 7½ in rolled down to 6 in. With hard limestone 6 in loose rolled down to 4¾ in.

Applying Screenings. In some specifications it is stated that the voids in the foundation course shall be filled with stone screenings, sand, or gravel, the fine binding material to be thoroly swept in, watered, and rolled. No surplus material, however, is allowed to remain on the surface of the foundation course. This method of construction provides a firmer foundation than where the voids between the stone are not so filled. The same treatment is also frequently used to facilitate the rolling of the foundation course where the stone is of such a character that it will not readily compact under the action of the roller. Screenings are generally used in connection with the construction of the upper course. When this course has been firmly compacted, the surface is covered with a layer of stone screenings and thoroly sprinkled with water, which washes the screenings into the voids in the stone. More screenings are added as desired and rolling is continued, the surface being sprinkled in front of the roller. When the proper amount of water and screenings has been used, a wave of grout will be pushed along in front of the roller. A coating of screenings should be laid over the entire surface, no more being used than is necessary to

cover the stone. The stone screenings resulting from the crushing of the rock with which the first two courses are filled are generally used for the binder.

Amount of Binder (3). The amount of binder required depends upon the character of the stone and upon the amount of rolling it has received before the binder is spread. If the voids after rolling are about 22%, the completed road having about 5% voids, enough binder must be added to fill about 17% of voids. The binder contains about 50% voids, so about 25% of binder will be required. For example, for trap macadam 15 ft wide, average thickness 5 in, 100 ft long, the amount of binder would be calculated as follows: $15 \times 100 \times 0.42 = 630$ cu ft per 100 lin ft; as 25% of 630 = 157 cu ft voids; screenings or binder weigh approximately 2500 lb per cu yd, or 93 lb per cu ft, $157 \times 93 = 7.2$ tons of binder required.

The Illinois Highway Commission's Instructions to Its Engineers (26) covering the construction of broken stone roads are as follows:

"PLACING STONE. On all roads except very narrow ones, the placing of stone should begin on the end nearest the stone pile and be carried from it so that the stone road will be available for hauling the stone. A 12-ft water-bound macadam, 8 in thick, requires 18 cu yd per 100 ft in each course of stone. To get this quantity the wagons should be measured and the capacity chalked on the sides, if they vary. If all are of practically the same capacity, it is unnecessary to mark them. In measuring, make liberal allowance for heaping above the boards. Having determined the capacity of the wagons, figure the distance each load should cover and give the dumper a stick, cut for the distance the wagons should be spaced when dumped. The loads should be dumped in the middle of the subgrade. If the loads vary, the measuring stick should have notches properly marked for each size of wagon. The usual tendency is to use too much stone and the amount used should be checked after each spreading, to be sure that the stone does not exceed the thickness shown on the plans. As an additional check, use the car weights of the stone, and determine whether at 2500 lb per cu yd it will cover the proper amount of roadway. The quantity of stone required for a road of any other width or thickness should be checked in the same manner.

"SPREADING STONE. When a sufficient amount of stone has been dumped, it should be spread with a road machine. The following method is most satisfactory: Set the blade square across the road and use two teams, hitched tandem, on the grader. For the first three or four trips, drive in the middle with the blade held level and drag the stone lengthwise of the road, allowing it to spread what it will, scraping only the tops of the loads at first. Then set the blade to throw material towards the shoulder and make the rounds on the sides, holding the blade to conform to the crown of the road. If depressions appear as the spreading progresses, do not add additional stone, but keep dragging with the grader until the surface is uniform. Give the stone a final touching up with hand rakes.

"HARROWING. Both courses of stone are to be harrowed after they are spread, but in no case should the harrow be expected to spread the stone or remove depressions. The use of the harrow is to bring the larger stone to the surface and to shake down any small material that may be mixed with it. The harrowing is also important on the top course of poured bituminous macadam to shake the dust from the individual stones, giving a clean surface for the bitumen. Usually three or four trips over a given area are required, but where the 2½-in stone comes very dirty, on account of cinders in the bottom of the car or under the storage pile, a greater amount of harrowing may be required. Dirty stone should never be used for the top course.

"ROLLING STONE. The roller must be run at not to exceed 100 ft per min. The rolling should begin at the edge of the macadam on lower course work, and the roller should work towards the crown line about half a wheel width at a trip. When one side has been gone over, the other side should be rolled and the rolling continued alternately on each side of the macadam until the stone is thoroly compacted. On the upper course the rolling should begin on the shoulder and should be done in the same general way as for the lower course except that it should begin 5 ft out on each shoulder. The condition of the surface must be studied carefully until it is properly compacted. The condition to be attained is to have the stone keyed together so that it will not be greatly disturbed by a load going over the surface. If Chester stone is used, it is possible to roll too much, causing the stone to spall. The Joliet stone, if rolled too

long, will wear smooth from abrasion under the roller and become loose. With either stone, therefore, the rolling must be watched carefully.

"SPREADING SCREENINGS. After the second course of stone has been properly rolled, the screenings shall be spread from piles dumped alongside the road. It will require from 4 to 5 cu yd of screenings per 100 ft of 12-ft road. The screenings should be dumped half loads in a place and hauled before the top course of stone is rolled, and must be dumped far enough from the stone to permit rolling the shoulder next to the stone. The screenings should be spread with square-end shovels, being whipped into the voids from the shovels. The screenings should not be thrown on the road surface in bunches. After the screenings have been spread, the surface should be gone over with a stiff brush to distribute the screenings uniformly. After the screenings have been spread, they should be watered lightly and allowed to stand. A good plan is to arrange the work so that the screenings are spread and watered just before the close of a day's work. In the morning a second light sprinkling may be applied and the surface rolled. If the screenings are of such a nature that when wet they stick to the roller, they should be wet by driving the sprinkler on the shoulder and spraying the water on the surface from one spray nozzle. Then allow the surface to dry until the roller does not stick, and roll thoroly. Repeat the process of wetting and rolling a few days after the first finishing and keep traffic off until the screenings set. In hot, dry weather, 2 days are sufficient; in cool weather, 4 or 5 days are required. The final rolling should be done driving the sprinkling wagon immediately ahead of the roller. The surface at this time should be so compact that the water flushes to the top under the action of the roller. Care must at all times be used not to apply so much water as to soften the subgrade. If this happens, keep the roller off that portion of the road until the foundation has had time to dry. After the road has been opened for traffic, watch carefully for any signs of raveling and patch them as soon as they appear. To do so, loosen the surface stones where the break appears, add a few additional stones, roll, cover with screenings, and sprinkle. When the road is opened to traffic, it should have from ¼ to ½ in of screenings on the surface."

10. Specifications for Construction

Am. Soc. Mun. Imp. (12). For sections covering physical properties and sizes of broken stone, see Art. 7.

"GENERAL DESCRIPTION. The broken stone road shall consist of three courses of broken stone, separately constructed, laid to conform to the required grades and cross-sections and constructed as hereinafter specified.

"FIRST COURSE. After the subgrade or subbase course shall have been prepared as specified, a course of No. 4 broken stone shall be evenly spread so that it shall have after rolling the required thickness of 3½ in. The depth of loose broken stone shall be gaged by the use of strings between iron stakes, as directed. The spreading of the broken stone must be from piles dumped on boards provided for the purpose or from piles dumped alongside the road, or as directed by the Engineer. This course shall be thoroly rolled with a 10 to 15-ton road roller. The rolling shall begin at the sides of the road and continue towards the center and shall be kept up until there is no disturbance of the stone ahead of the roller. After the completion of the rolling, no teaming other than that necessary for bringing on the broken stone for the next course shall be allowed over the rolled broken stone. Should it be apparent after the rolling of the first course that the subgrade material shall have become churned up into or mixed with the broken stone of this course, whether by reason of the rolling, or by hauling over the broken stone or otherwise, the Contractor shall at his own expense remove and replace such mixture of subgrade material and broken stone with clean broken stone of the proper size and shall roll the material to produce a uniform, firm and even first course as required.

"SECOND COURSE. On the completed first course shall be spread, in the manner specified in the preceding paragraph, No. 3 broken stone to form the second course. This broken stone shall be evenly spread to such a depth that it shall have after rolling the required thickness of 2½ in. After the second course shall be compacted under the same provisions as prescribed for the first course, it shall be evenly covered with a thin layer of screenings. The quantity of screenings to be used shall be just sufficient to cover the larger stones and care shall be exercised to avoid the use of an excess

of the screenings. This covering shall then be rolled as heretofore provided. When the rolling shall have been completed the surface of the second course shall be firm, even and true to the lines, grades and cross-sections.

"THIRD COURSE. On the completed second course shall be spread in the manner above specified for the first course No. 3 broken stone to form the third course. This broken stone shall be evenly spread to such a depth that it will have after rolling the required thickness of 2½ in. After the third course shall have been compacted under the same provisions as prescribed for the first course, it shall be evenly covered with a thin layer of screenings. The quantity of screenings to be used shall be just sufficient to cover the larger stones and care shall be exercised to avoid the use of an excess of the screenings. This covering shall then be rolled as heretofore provided except that water shall be used in connection with the rolling as follows: After the screenings shall have been lightly rolled, water shall be sprinkled on the road surface just ahead of the roller in such quantity as will prevent the sticking to the wheels of the roller of the fine material on the surface, and the combined spreading of screenings, watering and rolling shall be continued until the voids of the broken stone become so filled with the finer particles as to result in a wave of grout being pushed along the road surface by the front wheel of the roller. When the rolling shall have been completed the surface of the third course shall be firm, even and true to the lines, grades and cross-sections. After the third course has been compacted, puddled and filled as above specified, it shall be evenly covered with a thin layer of screenings. Should at any time, after its construction and prior to the acceptance of the road, the larger stone be visible in the surface of the road, the Contractor shall, without extra allowance, spread, sprinkle and roll sufficient screenings to completely cover the same.

"MEASUREMENT AND PAYMENT. The quantity of broken stone road to be paid for shall be the number of square yards, measured horizontally, satisfactorily completed in accordance with the specifications. The price stipulated shall include the furnishing, crushing and screening of the different sizes of broken stone, the placing, rolling and watering of the broken stone, and all work and expenses incidental to the completion of the broken stone road.

Mass. Highway Comm. specifications, substantially as used by many states, counties and municipalities in New England, are as follows:

"Before the surfacing is spread the road-bed shall be shaped to a true surface conforming to the proposed cross-section of the highway and rolled by a steam roller. All depressions occurring must be filled with suitable material and again rolled, until the surface is smooth and hard.

"Broken stone shall be spread and rolled on the road-bed prepared as hereinbefore described, as follows:

"The width of the broken stone shall be 18 ft.

"All broken stone used shall be laid in layers or courses. The lower course shall consist of stones that will pass thru a ring of 2½ in in diameter and will not pass thru a ring 1¼ in in diameter; the upper course shall consist of stones that will pass thru a ring 1¼ in in diameter but will not pass thru a ring ½ in in diameter.

"The lower course shall be 4 in deep at the center and 3 in deep at the sides after rolling. The upper course shall be 2 in deep at the center and 2 in deep at the sides after rolling.

"After the two courses above described are thoroly compacted, broken stone screenings shall be thinly spread over the stone surface, watered and rolled until the mud flushes to the surface. As the stone screenings are watered and rolled, voids between the larger stones will appear in the surface and this operation of thinly spreading the screenings, watering and rolling, and flushing out, shall be continued until the surface is completed to the satisfaction of the Engineer. Screenings so used shall not be larger than will pass thru a ½-in mesh sieve. Whenever the Engineer may direct, roads shall be allowed to dry out between periods of watering and rolling.

"Each course shall be rolled separately by a steam roller and evened up with material of the same size and quality as has been used in that particular course, and to the satisfaction of the Engineer.

"All broken stone shall be spread from carts by hand, or from a dumping board, or from self-spreading carts which shall be of a type approved by the Engineer. No soft or disintegrated stone shall be used.

"If so ordered by the Engineer the thickness of the broken stone shall be increased or diminished at such points as he may direct.

"The finished surface of the road shall present such crown as shall be directed by the Engineer."

New York Commission of Highways. "The sizes of all stone used under these specifications shall be determined by the size of screen aperture thru which the stone will pass when revolved in a rotary screen. They shall be designated as follows:

Diameter of Aperture Min.	Max.	
	¼-in square	Screenings
¼-in square	⅝-in circular	No. 1
⅝-in circular	1¼-in circular	No. 2
1¼-in circular	2¼-in circular	No. 3
2¼-in circular	3½-in circular	No. 4

"Broken stone shall be clean and sharp angled, shall pass the standard tests for abrasion and toughness as adopted by the Am. Soc. Test. Mat., and shall be approved by the Bureau of Tests and acceptable to the engineer before being used.

"Field stones, boulders or fence stones which are crushed for macadam purposes shall be 6 or more inches in diameter, if consisting of rounded cobbles. If of the flat variety, the minimum thickness shall be 2 in, which latter requirement will also apply to laminated quarry stone.

"If after trial it is found that partially developed quarries, ledges or other sources of supply do not furnish a uniform product, or if, for any reason, the product from any source, at any time, proves to be unsatisfactory to the engineer, said engineer may require the contractor to furnish stone from other sources of supply, and the contractor shall have no claim for increased payment on account of such requirement.

"The contractor shall furnish one or more stone crushing plants of type, composition, and capacity satisfactory to the engineer. The rotary screens shall be provided with openings of size and shape given under Stone Sizes, unless otherwise ordered by the engineer.

"All crushing plants installed on the work shall be fitted up with a tailing chute so that no stone will reach the bins other than that which passes thru the proper screen.

"All stone must be of the required size when placed in the roadway, and no breaking up of stone by hammers or otherwise will be permitted after the stone has been placed in the work.

"In no case shall any constituent of macadam pavement be dumped into place in mass; the final placing shall be by shovel or by thin spreading such that no appreciable fall occurs.

"The spreading of any layer or course of broken stone, gravel or filler, whether in foundation, bottom or top courses, shall be done from suitable spreader wagons or from piles dumped along the road as directed by the Engineer.

"No segregation of large or fine particles will be allowed, but the stone as spread shall be well graded with no pockets of fine material.

"The quantity to be paid for under this item shall be the number of cubic yards of compacted material in place in the completed course. The amount to be estimated shall be computed by multiplying the finished cross-section of the bottom course as shown on the plans or ordered by the Engineer, by the length of the bottom course measured along the axis of the pavement.

"After the subgrade or foundation course shall have been properly prepared and proper drainage provided, a course of broken stone or graded No. 3 or No. 4 size or a uniform mixture of same shall be spread evenly so that it will have after rolling the required thickness. If specifically allowed by the Engineer a limited amount of No. 2 stone may be used in the bottom course.

"In cases where the finished thickness of the bottom course is to be more than 5 in, the broken stone or gravel for it shall be spread, rolled and filled in two separate layers neither of which shall be of a greater depth than 6 in measured loose.

"The depth of loose stone in all cases, whether in foundation, bottom or top courses, shall be gaged by the use of cubical blocks of suitable size.

"After the bottom course of stone has been laid loose it shall be thoroly rolled with an approved roller weighing not less than 10 tons.

"This rolling must begin at the sides and continue toward the center and shall continue until there is no disturbance of the stone ahead of the roller. After the stone is thoroly compacted, No. 1 stone or gravel, and screenings or sand, or a mixture of these, shall be uniformly spread upon the surface and swept in with the rattan or steel brooms and rolled dry. After the completion of the rolling no teaming other than that necessary for bringing material for the next course shall be allowed over the rolled material. It is the intention to bind this course with the small stone, but not to use so much that a good bond will not be secured between the bottom and top courses.

"When two courses of bottom stone are laid each course shall be treated by rolling and adding fine material as described above.

"If the subgrade material shall become churned up into or mixed with the bottom or subbottom courses thru the Contractor's hauling over it or working on it when the subgrade is in a wet condition, the Contractor shall at his own expense remove such mixture of subgrade material and broken stone and replace it with clean broken stone of the proper size, and shall roll or otherwise compact the material so as to produce a uniform, firm and even bottom course.

"If the above condition occurs thru no fault of the Contractor, the Contractor shall be paid both for excavating and replacing under the items Excavation and Bottom Course respectively.

"All filler for top and bottom courses shall be delivered and piled alongside the road before the course in which it is to be used is placed.

"The top course shall, except as noted below, consist of No. 3 broken stone as shown on the plans and of the thickness shown thereon, together with the binder necessary to properly fill and bind the course. The binder shall consist of screenings and No. 1 stone mixed.

"The No. 3 stone shall be spread evenly upon the bottom course, using cubical blocks for gaging, to such a depth as to insure the required thickness after it shall have been thoroly rolled and compacted. Care shall be used in the spreading of the stone that no irregularities in the contour shall develop in the rolling; every such irregularity that does occur the Contractor shall remove before adding the smaller material. The rolling shall be done with a 10 to 12 ton self-propelled roller of approved pattern, and shall be continued until the layer of stone does not creep or wave ahead of the roller.

"After the stone has been compacted to the satisfaction of the Engineer, a light coating of binder shall be spread on dry by shovelling from piles previously placed alongside the pavement, and immediately swept in and thoroly rolled. Care must be taken thruout to add the binder only in light coatings and to thoroly sweep each coating in order that the maximum amount of binder may be worked in to fill the voids. The spreading and sweeping and rolling shall be continued until no more binder will go in dry, after which the macadam shall be sprinkled until saturated, the sprinkler being followed by the roller. If the subgrade should become wet to such an extent that the pavement becomes unstable and waves under the roller, the roller shall be taken off and this portion left to dry out before puddling is resumed.

"More screenings shall be added where necessary, and the sweeping, sprinkling, and rolling shall continue until a grout has been formed that shall fill all the voids and be pushed into a wave by the wheels of the roller. After the wave of grout has been produced over the whole section of the macadam this portion shall be left to dry out, after which it shall be opened to traffic. The macadam shall be repuddled and back-rolled on succeeding days as much as may be necessary to secure satisfactory results. The macadam shall then be covered with a wearing carpet of screenings at least ⅜ in thick; this wearing carpet shall be maintained and renewed until the whole road is accepted. During all the working hours when the roller is not needed for rolling the fills, subgrade, shoulders, and unfinished courses of the pavement, it shall be employed in back-rolling the earlier portions of the macadam."

Tennessee Method (36), used on an 8-mile section of the Memphis-Bristol Highway in Tennessee, consisted in separating the screenings into two sizes, one size being from ½ to ¼ in and the other the dust of fracture, and putting these two sizes on the road in separate operations. The adoption of the following specifications for building a water-bound broken stone road, both as to the method of proportioning the rock and as to sprinkling, is advocated.

1. The subgrade shall be thoroly rolled until it is firm and compact, with the proper crown of ¾ in per ft.

2. On this shall be placed 6 in of No. 1 grade rock, ranging in size from 1½ to 3 in. This shall be spread uniformly and rolled dry until the rock does not creep before the roller, or creeps just enough to set it in place without crushing.

3. Then 2 in of stone of No. 2 grade, ranging in size from ½ to 1½ in, shall be spread uniformly, sprinkled, and rolled thoroly into the voids of the No. 1 grade.

4. Then ¾ in of the coarse material from the screenings, consisting of sizes from ¼ to ½ in, shall be spread uniformly, sprinkled, and rolled thoroly into the voids of the No. 2 grade.

5. Finally, ¼ in of the dust from the screenings shall be spread, preferably by hand from shovels, thoroly soaked, and rolled to a finish.

"This method gave a surface which is virtually impervious to water and was less affected by automobile traffic than the ordinary type of broken stone road. From the contractor's point of view it was found practicable to care for 100 cu yd of broken stone per day with one 10-ton roller, while with other types of broken stone roads it was found difficult to properly roll one-half this quantity and secure the proper bond."

Road Board of England. "These general directions are intended for use in cases where a new surface coating is to be laid with steam rolled water-bound macadam on any road which has a proper foundation or subcrust of adequate thickness.

"Trial Trenches. Before laying the new surface the thickness of the old crust including the foundation should be ascertained by opening trial trenches at intervals averaging about 150 yd apart, extending from the side to the center of the road, such trenches to be made alternately on opposite sides of the road. A careful record of the facts disclosed by these trenches should be kept with plans and sections for future reference.

"If a proper foundation or subcrust of adequate thickness does not exist, or if the road is weak at the haunches, the following steps should be taken.

"In the case of heavily trafficked roads the haunches should be strengthened and the crust thickened either with stone of any kind suitable for bottoming work, broken to a gage of from 3 to 4 in, or with hard core, clinkers or other suitable materials, according to the nature of the subsoil. In some cases, where the surface of the broken stone after being steam rolled is sufficiently smooth for the purpose of traffic, it may be possible to allow the bottoming material to be used as the wearing surface of the road for a short period, not exceeding 12 months, if it is important for financial reasons to postpone for that period the laying down of the final surface coating in accordance with the other provisions contained in these general directions.

"Total Thickness of Crust. Even when there exists a good natural foundation, the total thickness of the road crust, including the old and the new macadam after consolidation by rolling, should not be less than 4 in. In the case of well drained subsoil, which cannot be materially softened by the infiltration of surface water, the total thickness, including the new consolidated surface coating as well as the subcrust and foundations, if any, should not under ordinary circumstances be less than 5 in. In the case of fairly hard clay or other yielding subsoils, the total thickness, including foundations, should not be less than 9 in. In the case of soft wet clay or bog or marshy subsoil, foundations of a special character may be required.

"Thickness of New Surface Coating. The thickness of the new surface coating of macadam when consolidated by rolling should be from 2 to 3 in, according to the traffic requirements. If it is desired that the new coating should have a greater thickness than 3 in when consolidated, the stone should be applied in two coatings separately rolled.

"Cross-Fall. The finished surface should have a cross-fall of 1 in 24, or ½ in to the ft. If the old crust is not sufficiently thick at the crown to enable this cross-fall to be obtained when a new coating of the thickness above mentioned is superadded, the old surface should be left intact and unscarified, and the thickness of the new coating of macadam should be increased as far as may be necessary. If the crust is of ample thickness, but the cross-fall excessive, it should be reduced by scarifying the surface and removing material from the crown to the sides previous to the application of the new coating. The material so loosened by scarifying should be screened, and all material finer than ½ in should be put on one side to be used for top dressing during rolling operations.

"STONE AND SCREENINGS. The road stone for the new surface coating should be stone of approved quality, broken as cubically as possible, and should contain about 70% of stone which will pass thru a 2½-in ring, but which will not pass thru a 1¾-in ring; about 20% which will pass thru a 1¾-in ring, but which will not pass thru a screen with rods ¾-in apart. The screenings forming the residue from the above, which will be obtained by the use of the ¾-in rod screen, should be kept separate and used as a top dressing during rolling operations.

"SPREADING. The stone must be spread by careful men selected for their knowledge and experience of such work, as the durability and evenness of wear of the surface obtained by steam rolled coatings greatly depend on judicious uniform spreading. The whole of the stone should be turned over in the process of spreading. Care must be taken not to allow the stone to be tipped upon the road close to the point of spreading, as this prevents a thoro turning over of the material in the act of spreading. When stones are transported by rail or by road over long distances, the different sizes of stone are liable to separate themselves, and it is important that during the act of spreading they should be well mixed so as to obviate the possibility of having larger stones on some parts of the road and smaller stones on other parts.

"Note. One ton to cover 8 to 9 sq yd may be taken as an average quantity required to give a consolidated thickness of 3 in.

"When stones are spread in thick coatings so that 1 ton covers less than 8 yd, there is a greater liability to unequal consolidation, inasmuch as stones are pushed in front of the roller until the roller surmounts them and thus a corrugated or wavy surface is formed.

"ROLLING. The rolling should be carried out by a roller of a weight of about 10 tons. This must be in charge of a skilled driver who has been specially trained for the purpose. The macadam should be consolidated by starting the work at the sides and gradually working towards the center. No water or binding should be applied until dry rolling has been carried out to a sufficient extent to form a smooth, hard surface with the correct cross-fall, with the stones well knit together and showing their faces on the surface. The cross-section of the newly rolled surface should be frequently checked by the use of a long straight-edge and level to insure that the cross-fall of 1 in 24 is correctly obtained. No spreading or rolling is to be carried out in frosty weather. When the road can not be entirely closed to traffic care should be taken to minimize inconvenience to the traveling public during the progress of the work by coating one-half the width at one time. No unrolled stone should be left on the road over night. Care should be taken not to leave a vertical or steep edge of the new coating, but the edge should be thinned out so as to afford an easy passage from the new coating to the old surface. Notice boards warning the public that steam rolling work is in progress should be placed at reasonable distances from each end of the work.

"BINDING. The binding material should be the best reasonably obtainable. It should be either of the same material as the new coating, or of granite, limestone, or slag chippings, or failing these suitable pit gravel, and the largest stone in it should not exceed ¾ in in its greatest dimension. The binding material is not to be applied until the stones have been tightly rolled as above described. It should then be spread, watered and swept over the surface during the final rolling operations, working it from the channels towards the center so as to fill the interstices or voids between the rolled stones. Care should be taken not to use more binding material or water than is absolutely necessary to insure proper consolidation. The success of water-bound steam rolling so greatly depends on the quality and quantity of the binding material used that extreme care should be taken in its selection and application.

"REROLLING. In some cases it is advisable that a steam rolled water-bound macadam surface should be lightly watered and rerolled from a week to a fortnight after the first rolling.

"RECORDS. A careful daily record should be kept of all particulars of the work, the number of men employed, the time occupied, the quantity of material used, the area of new coating finished, and also of the state of the weather and other details."

11. Construction Cost Data

Costs of broken stone roads are dependent upon availability of material and costs of labor. Local field stone is sometimes available, with short

hauls to a crusher located where both water and coal are conveniently near, all near the road to be constructed. In such a case the cost of the stone rolled in place on the road may be as low as $1.25 per ton, or about $3800 per mile of road 15 ft wide and 6 in thick. If, on the other hand, the stone has to be shipped a long distance by rail and then hauled a considerable distance by team or truck, the cost of the stone rolled in place on the road may exceed $3 per ton, or about $10 000 per mile.

Following is a list of items and costs making up the total cost of a broken stone road where the stone is imported to the work, the average haul from railroad being 2 miles, with labor at $0.22 per hr, and double team and driver, $0.60 per hr:

Crushed stone at plant	$0.60 per ton
Freight	0.55 per ton
Unloading from cars	0.07 per ton
Hauling	0.45 per ton
Spreading	0.05 per ton
Watering	0.07 per ton
Rolling	0.12 per ton
Total	$1.91 per ton

To the above costs must be added all overhead costs, including office forces and insurance, and if estimating for bidding, the profits must be added.

Using local field stone and a portable crusher the above list would be the same except that in place of the first three items there should be substituted the following:

Cost of stone at crusher	$0.50 per ton
Cost of crushing	0.25 per ton

Table VI.—Cost of Hauling Stone on Good Roads (22)

Road Number	Price per Hour of Teams	Length of Haul Miles	Cost per Ton Mile	Cost per Yard Mile
1	$0.50	1.8	$0.200	$0.240
1	0.50	1.2	0.240	0.288
2	0.62	2.0	0.200	0.240
2	0.62	1.7	0.215	0.260
2	0.62	1.1	0.230	0.275
2	0.62	0.6	0.250	0.300
2	0.62	0.2	0.500	0.600
3	0.62	3.0	0.170	0.205
3	0.62	2.75	0.175	0.210
3	0.62	2.5	0.175	0.210
3	0.62	2.0	0.190	0.230
3	0.62	1.75	0.215	0.260
3	0.62	1.5	0.230	0.280

Cost of Hauling Broken Stone by Motor Trucks (31) over macadam roads in New Jersey. "On the Jobstown Pike near Mount Holly, N. J., four 2-ton Autocar trucks, from Sept. 29 to Nov. 29, 1916, inc, hauled 3209 tons of 2½-in broken stone, 1714 tons of 1½-in and 250 tons of screenings, making a total of 5274 tons. During that time repairs and overhead charges amounted to $506.03, operating expenses were $373.87

and fuel $460, making a total cost of $1339.90. This sum divided by the total tons gives a unit hauling cost of $0.254 per ton of stone. The average round-trip haul was 5 miles. This reduces to a cost of $0.0508 per ton-mile. It is noticed that repairs plus overhead form the largest item, and these were the expenses that required vigilance.

"On this road contract, which included the rebuilding of a gravel road with 18-ft macadam, it was necessary to use teams for hauling gravel for binder and shoulders. These teams hauled 2 tons to a load and made 20 miles per day. Five dollars a day was paid for a team; therefore, it cost $0.125 per ton-mile to haul that material. This seems to afford a fair comparison with the above figures, as the trucks and teams were in use on the same work at the same time and under the same supervision."

Payment for Broken Stone Roads by the Cubic Yard. The usual practice is to pay for the actual cubical contents of the road crust as measured in place after rolling. In estimating cubic yards per mile of surface, multiply the width in feet by the average thickness in inches of the section, and then multiply this product by 16.2963; for example, a crust 1 mile long, 15 ft wide and 6 in thick, contains $15 \times 6 \times 16.2963 = 1466.67$ cu yd per mile. Similarly, to ascertain quantity per 1000 ft, a constant of 3.0864 is used; or, for same width and thickness as above, $15 \times 6 \times 3.0864 = 277.78$ cu yd per 1000 ft. The actual amount of stone used is often greater than the amount paid for in contracts, due to the settlement of stone into the subgrade during process of rolling, hence a contractor, if doing work by the cubic yard in place, should take this fact under consideration when preparing his estimate for bid. Before bidding a contractor should also note carefully the details in the specifications relative to use of binder or dust. Some specifications require the voids in the lower course to be filled with dust, thereby increasing the actual quantity of stone and dust in a cubic yard of finished road. Others call for a ½-in wearing surface of dust, which does not theoretically, but does practically increase the quantity of material per square yard or cubic yard, as it frequently disappears before the contract is finished and has to be replaced before acceptance. The quantity of water required for flushing varies, but will average about 10 gal to the ton of stone.

Payment for Broken Stone Roads by the Ton requires that scales be provided, as cubical contents cannot be accurately converted to tonnage basis. For purpose of approximate estimate it may be assumed that 1 sq yd rolled in place, 1 in thick, weighs 0.055 tons if of trap or other stone of high specific gravity, or 0.05 tons if of granite, limestone or other stone of medium specific gravity. This weight does not include the dust or binder, hence, in order to determine the approximate weight of stone in a road of given thickness, the weight of the binding dust must be added, which is approximately 0.048 tons per sq yd if of trap, and 0.042 tons per sq yd if of granite, regardless of the total thickness of the crust. From this may be obtained the following formulas, assuming t represents average thickness, and w, weight of section:

Tons per mile $= [(32.2667 \times t) + 28\ ]\, w$ for trap rock;
Tons per mile $= [(29.3333 \times t) + 24.5]\, w$ for granite and limestone;
Tons per 1000 ft $= [(6.1111 \times t) + 5.33]\, w$ for trap rock;
Tons per 1000 ft $= [(5.5556 \times t) + 4.66]\, w$ for granite and limestone.

For example, a crust one mile long, 15 ft wide and 6 in thick contains $[(32.2667 \times 6) + 28]\ 15 = 3324$ tons of trap rock, of which 15 by 28 tons or 420 tons is dust binder and 2904 tons is broken stone.

Payment to contractors by the cubic yard of stone as measured after rolling in place is preferred by some engineers, while payment by the ton is preferred by others. Those preferring to pay on a per ton basis claim that it is impossible to measure accurately the volume of stone; that a variation of ¼ in in depth makes an error of 8.33% in the determination of the volume, or from $300 to $400 per mile of 18 ft roadway.

Average Prices per Square Yard of Broken Stone Roads in various localities in the United States are given in Table VIII.

Methods and Cost of Resurfacing a Broken Stone Road with Rocmac Macadam (28). "The rocmac wearing surface was constructed in the following manner: Upon the rolled stone base of the old macadam road was deposited a layer of rocmac matrix about 1¼ in in thickness. Rocmac matrix consisted merely of a mortar made of limestone screenings mixed with rocmac solution. Rocmac solution is a liquid

silicate of soda, which reacts with carbonate of lime contained in the limestone screenings and assumes a set similar to that of Portland cement altho differing markedly from Portland cement in that chemical action is not completed immediately but is recommenced with each addition of moisture after the road is completed. This fact tends to prevent the wearing of holes since abraded parts of the surface heal over after a rain. The rocmac matrix, or mortar, was covered with 4 in of coarse crushed stone and rolled. This rolling forced the stone down into the matrix, filling the voids in the stone. As the matrix rose to the surface it was broomed forward and diagonally across the road and rolling continued until a smooth even surface was secured. The road surface was then sprinkled with dry limestone screenings. Table IX gives the detailed cost of this work. The resurfacing was accomplished by day labor.

Table IX.—Cost of Resurfacing Old Macadam with Rocmac Macadam in Queen Victoria Park, Canada

	Total	Per Sq Yd Cents
Labor		
Removing old surface, 96 cu yd	$97.20	11.26
Hauling 144 cu yd of stone and screenings from Victoria Park station	119.08	12.80

	$742.94	86.08

12. Slag and Shell Roads

Slag roads and shell roads have been used to a limited extent thruout the United States. As the details of construction are similar to those employed in the construction of broken stone roads, certain features, peculiar to each, are described in this section.

Slag Roads. Blast furnace slags are produced in the manufacture of iron and steel and, in some cases, are very similar in appearance to close-grained igneous rocks. In reducing iron ores, the impurities rise to the surface, as the iron melts in the furnace, and unite with the fluxing material. This material is drawn off in a molten condition and is cooled either in water or in the air. Sometimes it is turned out onto the ground in a semi-molten condition and forms large banks of slag. In some cases, blast furnace slag may be excavated from slag banks by means of a steam-shovel, which serves to sufficiently break up the material so that it may be screened. In converting the iron from the blast furnaces into steel by the open-hearth process, more flux is used in the process, which rises to the surface of the molten mass as slag. The slag from the open-hearth process is generally run into molds It has, in some cases, been broken up in a rock crusher into sizes suitable for road work.

Slag is used for foundation courses and in some instances to form the entire road crust. The methods used are similar to those described for the construction of broken stone roads. Slag composes the mineral aggregate of the Tarmac pavements, which are built extensively in the County of Notts and elsewhere in England (see Sect. 16).

Shell Roads. The State of Maryland has built many miles of oyster shell roads along the eastern shore of Chesapeake Bay. The shells are about the only available material for surfacing roads in that locality. Where the shells are simply thrown onto the old roadbed without previously shaping the latter, the results obtained are not very satisfactory. The shells soon push down and the mud works up, producing conditions which are not much better than before the road was improved. If the traffic follows in the same track on a shell road, ruts will be quickly formed and a horse path will be made in the center. If these low places are immediately filled with new shells, it will tend to make the traffic distribute itself over the surface and prevent, to a great extent, subsequent tracking. Shell roads, unless watered or treated with some form of dust palliative or bituminous surface, are liable to be very dusty.

Maryland State Roads Commission Specifications stipulate that the subgrade shall be firm and well rolled. The depth of the first course of shells is either 5 in or 5 in at the center and 3 in at the sides. The depth of the second course is either 3 in or 5 in at the center and 3 in at the sides. The shells are spread upon the roadbed with shovels from piles along the road or from a dumping board. They are rolled with an 8-ton roller and are sprinkled with water or bound with sand during the process of rolling until the surface is firmly compacted. The third course is composed of clean, sharp sand, spread just thick enough to cover the second course after the latter has been thoroly compacted. Shell roads cost from 40 to 50 cents per sq yd.

MAINTENANCE

13. Causes of Wear

The length of time a broken stone road will last under traffic depends principally upon the amount and nature of the traffic. If traffic is light, a broken stone surface may last 15 years if originally built of good stone on a good foundation.

Water, if allowed to stand on a broken stone surface, will soften the latter and cause it to rapidly wear out. When the frost is coming out of the ground in the spring, the surface will also be in a soft condition and require attention. The effect of horse-drawn vehicle traffic is frequently observed in the formation of the horse path, so-called, in the center of the road. If the surface is given a flat crown, this will be prevented to some extent since the traffic will be encouraged to use the entire width of surface. If the teams track each other the wheels will form ruts, particularly when the road is in a soft condition. The grinding action of the wheels wears the stone and forms dust which, in a dry state, is swept away by the wind, thus leaving the stones in the top course exposed, in which condition they are liable to be displaced by the action of traffic. A heavy traffic of motor-cars travelling at high speed will also cause the broken stone surface to ravel very quickly when the mosaic of the upper course is exposed. Sometimes when the road is in this condition and the weather has been dry, a concentrated motor traffic of only one or two days' duration will cause ravelling.

"Interstitial Wear (13). It therefore appears that a load cannot be applied at any place on the macadam surface without producing a cone of some sort below it in which the macadam is further compressed; also, if the load is sufficient to cause any sinking whatever of the surface, a crack will be formed between the cone and the unloaded parts of the mass. As the load moves this crack and all the commotion below move along with it, and the whole mass, from the top to very near the bottom, is set in motion in its turn. In this movement the stones, big and little, are forced into new positions. Not one of them moves until it is pushed, and if it is not forced into a cavity already formed, it is forced against something else which opposes the movement. If this obstacle does not yield the pressure may be great enough to break it. It is easier to displace or to crush a small stone than a large one, and the smaller it is the more easily it is dealt with. The net result of the movement under the passing load is that the whole mass is being ground up into smaller fragments; the larger pieces get their corners and edges broken off, and the angular, flat-sided pieces of the original mass become like rounded pebbles. The moving load makes these bigger pieces act like the pebbles in a cement grinding mill; the smaller pieces are broken down to sand, and the sand is ground down to mud, or to dust, according to circumstances."

14. Methods of Maintenance

Maintenance of a broken stone road should begin as soon as the construction ceases. Ordinary repairs should be accomplished under what is called the continuous system of maintenance, that is, a system where the roads are constantly looked after and any necessary repairs are immediately made. Not only is the continuous system of maintenance the cheapest in the end, but it also keeps the road in a good state of repair. The patrol system of maintenance as carried out in France is a good illustration of what can be accomplished by this method.

Ordinary Repairs. To provide against failure from any of the causes enumerated in Art. 13, the following essential principles of maintenance work are given. At all times the surface of the road should be kept smooth. This enables the road to shed water more readily and eliminates shocks which would result from the traffic where the surface is uneven. Any hollows or pot-holes, which develop in the surface, should be repaired as soon as formed. Particular attention should be given to eliminating the ruts, since any depressions in the surface hold water, and are enlarged very rapidly by the action of traffic. Broken stone of the same size as is used in the upper course should be used in filling in the depressions and ruts. In France and England, it has been found that, in repairing pot-holes, the best

results are obtained if the holes are cut out on the lines of a square or rectangle which is of sufficient area to include the depression, the sides to be cut thru for the full depth of the wearing course. The stone is replaced, carefully tamped, filled with screenings, and puddled, or it is incorporated with some bituminous material either before or after placing. Rolling in the spring of the year, when the road is soft, will be of great help in providing a smooth surface for the remainder of the season. An excess of dust or mud on the surface should be removed, since dust is not only very objectionable from the standpoint of comfort to the traffic, but when wet it forms mud, which keeps the surface of the road in a moist condition, sometimes for a long period. On the other hand, when the upper course of stone presents a mosaic surface, sand, stone screenings, or other binding material should be spread on the surface to prevent ravelling. The surface is best preserved, however, by applying, to the swept surface of the road, a film of asphaltic oil or tar, which acts as a binder and dust layer.

The earth shoulder between the stone surfacing and the ditch should be trimmed up from time to time, so that water flowing from the surface of the road will not be impeded in its progress to the ditch. This work can, in many cases, be done in a satisfactory and economic manner by the use of a road scraper. The material removed from the shoulders, however, should never be thrown up into the center of the stone surface. As is the case in earth and gravel roads, the ditches and drains should be carefully looked after to provide for the ready flow of water.

Resurfacing. It is customary to resurface a broken stone road as soon as the top layer of stone is worn thru. The method of resurfacing depends upon the thickness of the layer of stone to be added. If 2 in or less in thickness of stone is to be added, the surface of the old road should be lightly scarified or loosened, in order to get a suitable bond between the old surface and the new; stone should then be spread and rolled in the same manner as in the laying of the upper surface in new construction (see Art. 9). If 3 in of stone is to be added it is not necessary to disturb the old surface before adding the new.

15. Maintenance Cost Data

The cost of maintenance varies with the quality and cost of materials, cost of labor, climate, amount and character of the traffic and the condition in which the road is maintained.

The cost of maintaining a broken stone road per square yard per annum in several localities is as follows:

London. Heavy traffic streets, \$0.6250; moderate traffic streets, \$0.2975; light traffic streets, \$0.1450; lightest traffic streets, \$0.0625.

In the Department of Havre, France, for departmental roads in cities, it is \$0.03, and in the country, \$0.018 per sq yd per annum.

Massachusetts state roads before the advent of the automobile was about \$0.01 per sq yd per annum.

It is evident that a more durable type of road should have been constructed where the maintenance costs are as high as that given above for the streets of London. Water-bound broken stone roads with a light traffic can be economically maintained with an application of light oil or tar applied cold at the rate of about $^3/_5$ of a gal per sq yd, at a cost of about \$0.03 per sq yd per year.

SECTION 12

BITUMINOUS MATERIALS

BY

PRÉVOST HUBBARD

CHEMICAL ENGINEER, UNITED STATES OFFICE OF PUBLIC ROADS AND RURAL ENGINEERING

HYDROCARBONS

1. Composition and Classification of Hydrocarbons

Bitumen. The bitumen of bituminous materials used in highway engineering consists mainly of hydrocarbons and almost invariably lesser amounts of their sulphur, oxygen, and nitrogen derivatives, all of which are soluble in c.p. carbon disulphide. These hydrocarbons and their derivatives are practically innumerable and occur as complex mixtures, solutions, and emulsions. There are no known methods for separating and identifying all of the hydrocarbons and hydrocarbon derivatives present in bituminous materials, and in the routine examination of these materials none of the individual hydrocarbons are determined either qualitatively or quantitatively. There are a number of series or families of hydrocarbons, however, whose presence is readily detected by comparatively simple chemical tests. The various members of any given series possess many characteristics common to all, and the predominance of certain series therefore controls to a great extent the general characteristics and behavior of the bituminous materials in which they occur. For this reason it is essential that the highway engineer should acquaint himself with the properties of at least the more important hydrocarbon series if he wishes to use bituminous materials to maximum advantage. This involves an elementary knowledge of the variations in structure of hydrocarbon molecules.

Hydrogen (H) is the lightest known chemical element. It has an atomic weight of 1.01. A single hydrogen atom cannot combine with more than one atom of any other element. Its chemical affinity or valence is therefore one, and it is termed a monovalent element. It is an invariable

constituent of hydrocarbon molecules, and therefore of all bituminous materials. At very high temperatures it may be split off in an atomic or elemental state from hydrocarbon molecules, leaving behind a molecule richer in carbon, or else the element carbon itself. The hydrogen molecule is composed of two hydrogen atoms expressed H_2 or H − H. In the molecular state it is a rather inert, colorless, and odorless gas. In the atomic or nascent state, which it only transiently assumes, it is a powerful reducing agent or oxygen remover. In this capacity it unites with oxygen to form water. Oxidation, which is the opposite of reduction, may consist either in the addition of oxygen, its substitution for another element in a compound, or in the removal of hydrogen from a compound by means of oxygen or other oxidizing agent.

Carbon (C) has an atomic weight of 12.01, almost twelve times that of hydrogen. One atom of carbon can combine with four atoms of hydrogen, which is monovalent. Its chemical affinity is therefore four, and it is called a tetravalent element, altho with certain elements other than hydrogen it sometimes also exhibits a valence of two. It is a necessary constituent of hydrocarbon molecules, and therefore of all bituminous materials. Like hydrogen, at very high temperatures it may be split off in an atomic or elemental state from hydrocarbon molecules with the formation of lighter hydrocarbon molecules or the element hydrogen. Unlike hydrogen, it is non-volatile. It occurs as an element in three forms, as diamond, graphite, and amorphous carbon. This variation in form is believed to be due to different ways in which the carbon atoms are arranged in the carbon molecule, and the molecules in the masses. The amorphous form, as coke, lamp-black, or soot, is of most interest from the standpoint of bituminous materials. At ordinary temperature carbon is chemically inert, but at high temperatures it is a reducing agent and in this capacity unites with oxygen to form carbon dioxide or carbon monoxide.

Hydrocarbon Molecules exist in an almost infinite number of forms, some of which are exceedingly complex. The molecular weight of any hydrocarbon molecule is the sum of the atomic weights of hydrogen and carbon, each of which has been multiplied by the number of hydrogen and carbon atoms respectively which are present in the molecule. For all practical purposes the atomic weight of hydrogen is considered as 1 and the atomic weight of carbon as 12. Example: mol. wt. $C_2H_6 = (2 \times 12) + (6 \times 1) = 30$. The molecular weight of hydrocarbon molecules in general increases with the number of carbon atoms present in the molecule. No hydrocarbon molecule can contain more than 25.2 % hydrogen nor less than 74.8 % carbon. At ordinary temperature some hydrocarbon molecules are gases, some liquids, and some solids. At elevated temperatures many of the solid and liquid hydrocarbons assume the gaseous form without chemical change; also solid hydrocarbons may assume the liquid form without chemical change. At higher temperatures, depending upon individual hydrocarbons, molecules containing more than two carbon atoms may split into two or more different hydrocarbon molecules. When this occurs the original molecule is said to be cracked. If the cracking sets free the element carbon, the original hydrocarbon is said to be coked, and the operation involving such coking is termed destructive. If hydrocarbon molecules are subjected to elevated temperatures in the presence of air or oxygen, they may become oxidised. If they are subjected to elevated temperatures in the presence of hydrogen, they may be reduced. Cracking, coking, oxidising, and reducing reactions are produced in many

of the common manufacturing operations in connection with bituminous materials. They may also be produced during the manipulation of these materials in highway engineering. They frequently result in important and sometimes in injurious modification of the bituminous material involved, and for this reason they should be clearly understood by the highway engineer. They will be considered in detail later in this Section.

Hydrocarbon Radicals may be considered as hydrocarbon molecules from which have been removed one or more hydrogen atoms, leaving an equivalent number of free valences, which are extremely ready to unite with each other or with atoms which also carry free or unsatisfied valences. Thus three radicals may result from the removal of one, two, or three hydrogen atoms from the hydrocarbon molecule CH_4. The valence of these radicals is expressed by one, two, or three dashes placed after the radical formula, as follows: CH_3-, $CH_2=$, $CH\equiv$. Because of their extreme chemical activity, radicals can exist only transiently. They differ from true compounds in the fact that the latter carry no free valences, as all of the valences are satisfied within the molecule itself. Hydrocarbon radicals play an important part in determining just what compounds are ultimately formed in the processes of cracking, coking, oxidation and reduction of bituminous materials, as they are often produced as transient intermediate combinations of hydrogen and carbon during these processes.

Saturated Hydrocarbons are hydrocarbon molecules in which all adjacent carbon atoms are connected by not more than one valence, graphically shown as follows: $C-C$. Each valence not taken up by adjacent carbon atoms connects with or is satisfied by a hydrogen atom. Saturated hydrocarbons are quite stable and not prone to chemical changes. They therefore impart chemical stability to bituminous materials in which they occur, the extent of this stability depending upon the amount or proportion of saturated hydrocarbons present in the bitumen of the bituminous materials.

Unsaturated Hydrocarbons are hydrocarbon molecules in which at least two adjacent carbon atoms are connected by two or three valences, graphically shown as follows: $C=C$, $C\equiv$. Each valence not taken up by an adjacent carbon atom is satisfied by a hydrogen atom. It is evident that no two adjacent carbon atoms in a hydrocarbon molecule can be connected by four valences, because there would then be no valences available for hydrogen which is a necessary constituent of hydrocarbons. Unsaturated hydrocarbons are invariably less stable than saturated hydrocarbons because of the tendency of the double or triple bonds to break down to single bonds, thus producing radicals which unite with each other or with reactive atoms to form new molecules which are saturated. In general, the greater the number of unsaturated valences between carbon atoms the less stable becomes the compound. Unsaturated hydrocarbons therefore tend to produce chemical instability in bitumens or bituminous materials in which they occur, depending upon the proportion of unsaturated hydrocarbons and the extent of their unsaturation.

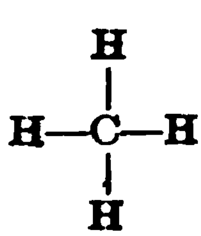
Open Chain Hydrocarbons are those in which the carbon atoms are linked to each other in such manner that their form may be graphically represented by an open chain, thus $C-C-C-C$. Side chains may also extend from any of the intermediate carbon atoms in the main chain, but in no case are the end carbon atoms of the same or different chains connected to form a closed chain or ring of carbon atoms within the molecule. Two or more adjacent carbon atoms in the open chain may be connected by more than one valence, so that open chain hydrocarbons may be either

saturated or unsaturated. Under certain conditions of temperature and pressure a number of unsaturated open chain hydrocarbon molecules may unite to form a single closed chain molecule. When this occurs it is at the expense of some or all of the multiple valences present in the reactive molecules which break down to a lesser number of valences between adjacent carbon atoms.

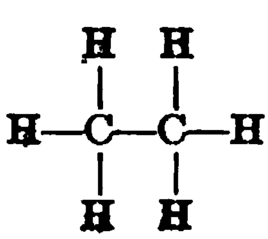
Cyclic Hydrocarbons are those in which some or all of the carbon atoms are linked in a closed chain, ring, or cyclic nucleus, thus . Open side chains of carbon atoms may extend from one or more of the carbon atoms which form a cycle, or a number of cycles may be linked together in a single molecule. Molecules which contain but one carbon cycle are known as monocyclic, those which contain two cycles are dicyclic. The general term polycyclic is applied to hydrocarbons which contain a number of cycles in the molecule. When two carbon cycles have a number of carbon atoms common to each other, the molecule is said to possess a condensed nucleus. If three carbon atoms are common to two cycles the molecule is sometimes called a bridge compound. In cyclic hydrocarbons two or more adjacent carbon atoms, either within the cycle itself or in a side chain attached to the cycle, may be connected by a double linkage. Cyclic hydrocarbons may therefore be either saturated or unsaturated. When the double linkage occurs in a side chain, chemical stability is usually less than when the double linkage is in the cycle. Under favorable conditions of temperature and pressure, cyclic hydrocarbons may break down into open chain hydrocarbons. The most common form of carbon cycle consists of six carbon atoms. No single cycles contain more than seven carbon atoms.

2. Open Chain Series of Hydrocarbons

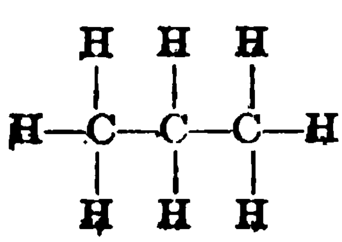
The Paraffin Series of hydrocarbons comprises the entire group of saturated open chain compounds. The general molecular formula for all of the members of this series is C_nH_{2n+2}. The simplest possible hydrocarbon and the only one which contains but a single carbon atom is the parent member of this series. Its name is methane and its simple molecular or empiric formula is CH_4. The next member containing two carbon atoms is ethane, C_2H_6; the third member, propane, contains three carbon atoms C_3H_8. Each succeeding member contains one more carbon atom and two more hydrogen atoms than the preceding member. This constant difference of CH_2 between adjacent members of a given series is common to all of the hydrocarbon series, which are therefore homologous. The graphic or constitutional formulas for the first three members of the paraffin series together with the monovalent, divalent, and trivalent radicals derived from each are as follows:



Methane CH_4



Ethane C_2H_6



Propane C_3H_8

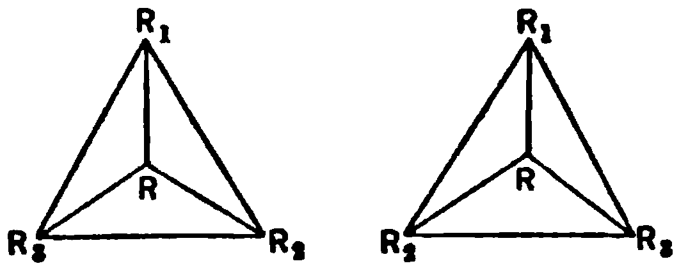
Radicals

Methyl $-CH_3$	Ethyl $-C_2H_5$	Propyl $-C_3H_7$
Methylene $=CH_2$	Ethylene $=C_2H_4$	Propylene $=C_3H_6$
Methenyl $\equiv CH$	Ethenyl $\equiv C_2H_3$	Propenyl $\equiv C_3H_5$

It will be seen that the nomenclature of the radicals is derived in all cases directly from the parent hydrocarbon, the ending yl being given to monovalent radicals, ylene to divalent radicals and enyl to trivalent radicals. Moreover, it may be seen that the members of this series, after methane, may be considered as combinations of two or more radicals. Thus ethane is composed of two methyl radicals linked together so that all valences are satisfied. Propane may be considered as a combination of the radicals methyl and ethyl or of two methyl radicals and one methylene radical. The first four members of the paraffin series are gases at ordinary temperature and pressure; the members containing from 5 to 15 carbon atoms are liquids, and those containing over 15 carbon atoms are solids. As the number of carbon atoms in the molecule increases certain other physical differences are found to exist. These differences are generally observed between the members of any given series (see Art. 4, RELATIONS EXISTING BETWEEN MEMBERS OF THE SAME SERIES). The paraffin hydrocarbons are more stable chemically than any other series. They are not acted upon by concentrated sulphuric acid, fuming sulphuric acid or nitric acid at ordinary temperatures. They are mutually soluble in one another. Thus, the solid paraffins are readily dissolved by the liquid paraffins of low molecular weight. The lighter liquid paraffins are not perfect solvents for the solid hydrocarbons of certain other series. For such compounds, however, the solvent action increases with the number of carbon atoms present in the liquid paraffin molecules. The solid paraffins unlike the solid members of other series are practically insoluble in a very cold mixture of alcohol and ether. This fact is made the basis of a method for determining the percentage of scale paraffin in bituminous materials. Paraffin hydrocarbons, both liquid and solid, are essentially greasy and exhibit but little cementitiousness. They predominate in certain petroleums. See Art. 15, PARAFFIN PETROLEUMS.

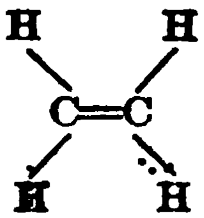
Isomerism. When two molecules or compounds contain the same elements in the same proportion but differ in structure or constitution, they are said to be isomeric and are termed isomers of one another. Isomerism exists to a marked extent among the hydrocarbons and plays an important part in the make-up and characteristics of bituminous materials. There are two forms of isomerism of particular interest: (1) Metamerism and (2) polymerism. In metamerism the isomers have the same molecular weight. In polymerism the isomers, while of the same percentage composition, have different molecular weights. Metamerism is a common phenomenon with nearly all of the paraffin hydrocarbons. The members of this series cannot polymerize, however, and polymerism will therefore be described under certain of the other series. The ordinary forms of metamerism may be graphically illustrated in formulas of two dimensions. Starting with the fourth member of the paraffin series, C_4H_{10}, the graphic formula may be represented in two ways.

1. 
2. 
The first formula shows the single chain or normal constitution, while the second formula shows the introduction of a side chain. The first compound is known as normal butane; the second as isobutane. The essential difference lies in the relative position of the carbon atoms to one another, which modifies both the chemical and physical properties of the materials, altho both have the same empiric formula C_4H_{10}. The next hydrocarbon of the paraffin series, C_5H_{12}, has three isomeric forms and as the number of carbon atoms in the molecules increases the number of isomers rapidly multiplies. Thus the hydrocarbon, $C_{13}H_{28}$, has 802 isomers. As the known normal paraffins run as high as $C_{60}H_{122}$, it is evident that the possible isomers for this compound are almost beyond comprehension. Another form of metamerism which is of considerable interest involves the conception of a three-dimensional or asymmetric carbon atom which has the form of a tetrahedron. Each apex of the tetrahedron represents a valence. If different univalent atoms or radicals are attached to these valences it is possible to arrange them so as to obtain isomers. Thus with four radicals which may be represented by the letters R, R_1, R_2, and R_3 the following isomers may be produced:

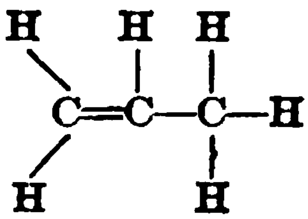


It is evident that from a given viewpoint R, the radicals are read in order from left to right or clockwise in the first illustration, while in the second they are read from right to left, or counter-clockwise. This form of isomerism is known as space or stereo isomerism. Many of the space isomers are optically active and when present in solution will rotate a beam of polarized light, passed thru the solution, to the right or to the left as the case may be. Those which rotate to the right are termed dextro rotatory and those which rotate to the left are termed laevo rotatory. Certain petroleums are optically active due to the presence of stereo isomers and this fact has been made the basis for identifying their source or origin. See Art. 13, FORMATION OF PETROLEUMS.

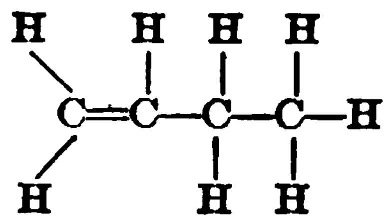
The Olefine or Ethylene Series of hydrocarbons comprise the open chain unsaturated compounds which contain one pair of adjacent carbon atoms connected by two valences. The general molecular formula for all members of this series is C_nH_{2n} and the common difference CH_2 exists between adjacent members. The first member of this series, ethylene, contains two carbon atoms, and its empiric formula is C_2H_4. The next member is propylene, C_3H_6. The graphic formulas for the first three members are as follows:



Ethylene C_2H_4



Propylene C_3H_6

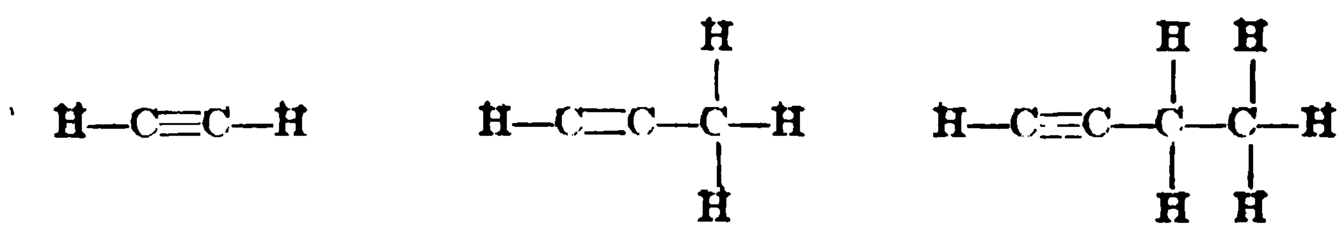


Butylene C_4H_8

It will be noted that the nomenclature of these compounds is identical with that of the divalent radicals of the paraffin series. Their relative structure should not, however, be confused, as the former are satisfied

molecules while the latter are merely partial compounds or collections of atoms which have free valences. Like the paraffins, the first few members of the olefine series are gases at ordinary temperature and pressure. The members containing from 5 to 20 carbon atoms are liquids and the higher members are solids. From the second member up isomerism occurs, as in the paraffin series, due to the introduction of side chains instead of a prolongation of the main chain of carbon atoms. In addition, the olefines exhibit the phenomenon of polymerism in which a number of molecules combine to form a single molecule. Thus three ethylene molecules polymerize to a single cyclic molecule containing six carbon atoms in the cycle, as follows: $3C_2H_4 = C_6H_{12}$. It is evident that the percentage of hydrogen and carbon in these two molecules is the same but that molecular formulas and molecular masses are different. These facts distinguish polymerism from metamerism (see Art. 2, ISOMERISM). Polymerism of hydrocarbons may be considered as isomerism of members of different series. The olefine hydrocarbons are much less stable chemically than are the paraffin hydrocarbons. They are readily acted upon and combine with sulphuric acid at ordinary temperature and may thus be separated from the paraffin hydrocarbons. They are mutually soluble in one another and are better solvents for the solid hydrocarbons of certain other series than are the corresponding members of the paraffin series. The solvent action of the liquid olefines increases with the number of carbon atoms in the molecule. The olefines are normal constituents of all petroleums but seldom if ever predominate in bituminous materials. The liquids and solids are essentially greasy and non-cementitious. The olefines are of particular interest, however, in the fact that by polymerization they produce hydrocarbons of other series which often predominate in bituminous materials of an asphaltic nature and possess certain desirable characteristics.

The Acetylene Series of hydrocarbons comprise the open chain unsaturated compounds which contain one pair of adjacent carbon atoms connected by three valences. The general molecular formula for this series is C_nH_{2n-2} and the common difference CH_2 exists between adjacent members. The first member, acetylene, which is a gas, has the empiric formula C_2H_2. Graphic formulas for the first three members are as follows:



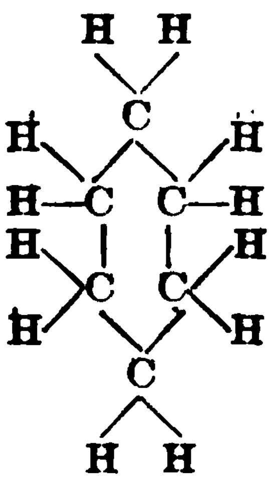
Acetylene C_2H_2 Allylene C_3H_4 Ethyl Acetylene C_4H_6

Metamerism exists among members of the acetylene series and like the olefines a number of molecules may polymerize to form a single molecule of another series. Thus three acetylene molecules will polymerize under suitable conditions to form a cyclic molecule containing six carbon atoms in the cycle as follows: $3C_2H_2 = C_6H_6$. The acetylene hydrocarbons are even less stable chemically than are the olefines. Like the olefines they are readily acted upon by sulphuric acid. They occur to only a very limited extent in bituminous materials but are of especial interest because by polymerisation they produce hydrocarbons of other series which predominate in tars and give to them peculiar characteristics essentially different from other types of bituminous materials.

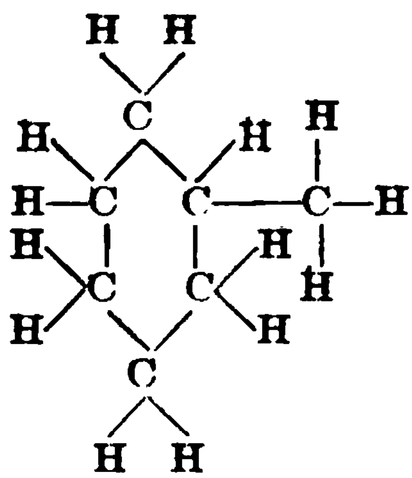
Other Unsaturated Open Chain Series. There are a number of other highly unsaturated and unstable open chain series which are of less importance than the foregoing. They are of interest, however, as being isomers of hydrocarbons in other series which predominate in certain bituminous materials. Among them may be mentioned the diolefines with the same general formula as the acetylenes C_nH_{2n-2}, the olefine acetylenes C_nH_{2n-4}, and the diacetylenes C_nH_{2n-6}.

3. Cyclic Series of Hydrocarbons

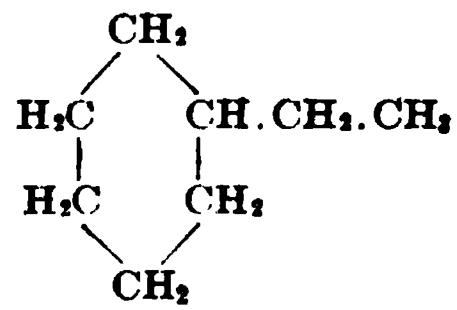
Monocyclic Polymethylenes. The monocyclic polymethylenes comprise a number of series of hydrocarbons which include all of the saturated monocyclic compounds. There are five of these series: the trimethylene series with three carbon atoms in the cycle; the tetramethylene series with four carbon atoms in the cycle; the pentamethylene series with five carbon atoms; the hexamethylene series with six carbon atoms; and the heptamethylene series with seven carbon atoms in the cycle. All of them have the general formula C_nH_{2n}, which is the same as that of the olefines. Of these series the hexamethylene is of most common occurrence and generally the most important. The hexamethylenes are commonly called NAPHTHENES and the first member of the naphthene series is termed hexamethylene or hexahydrobenzene. It has the empiric formula C_6H_{12}. The next member is C_7H_{14}, and each succeeding member differs from its adjacent members by CH_2. The graphic formulas for the first three members of the naphthene series are as follows:



Hexamethylene or Hexahydrobenzene C_6H_{12}



Hexahydrotoluene C_7H_{14}

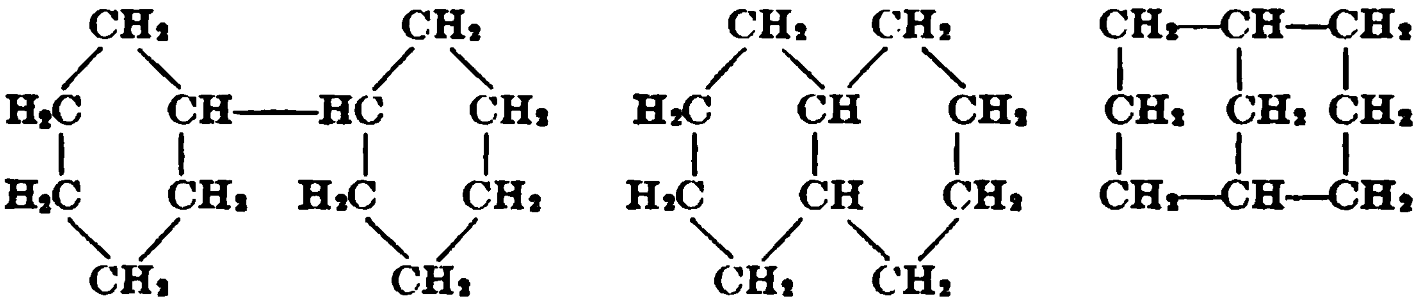


Hexahydroxylene C_8H_{16}

The known naphthenes are liquid hydrocarbons. Isomers are found from the third member up, but in the series proper isomeric modification occurs in the side chains and never results in a modification of the six carbon cycle or nucleus. The first member may be considered as being composed of six methylene radicals (see Art. 2, THE PARAFFIN SERIES) or as the result of polymerization of three ethylene molecules. Altho not so stable chemically as the paraffin hydrocarbons, the naphthenes are not acted upon by sulphuric acid as are the unsaturated open chain hydrocarbons. They are, however, broken up by the action of nitric acid, and it is believed that the higher members are readily acted upon at elevated temperatures by sulphur and oxygen (see Art. 20). They are mutually soluble in one another and are better solvents for the solid hydrocarbons of certain other

series than are the corresponding members of the paraffin series. Their solvent action increases with the number of carbon atoms in the molecule. The naphthenes are normal constituents of petroleums and occur to a marked extent in those of the semiasphaltic type. They are closely associated with those hydrocarbons which predominate in asphaltic petroleums and asphalts.

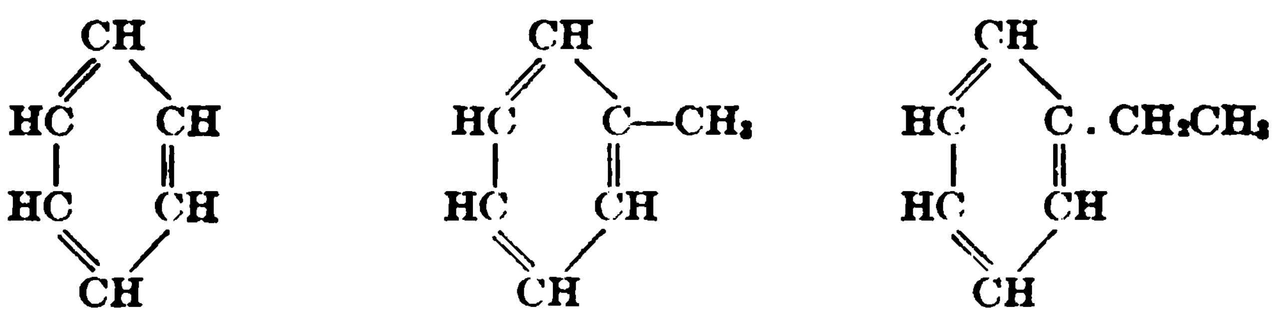
The Polycyclic Polymethylene Series include all of the various polymethylene series which contain two or more polymethylene nuclei. Their general formulas are C_nH_{2n-2}, C_nH_{2n-4}, C_nH_{2n-6}, etc. The nuclei may be individual and connected by a single valence or they may be condensed and have two or three carbon atoms in common. The following graphic formulas illustrate the three types above mentioned.



$C_{12}H_{22}$ $C_{10}H_{18}$ C_9H_{16}

The third formula represents a type of hydrocarbons which are known as bridge compounds. But little is known of the individual members of the polycyclic polymethylene series except that their structure is extremely complicated and that many of them possess unsaturated side chains which make them susceptible to the action of sulphuric acid without destroying the carbon nuclei. The bridge compounds in particular are believed to predominate in asphaltic petroleums and asphalts and to impart to these bituminous materials their cementitious character. Their chemical stability depends upon their degree of saturation. The higher solid members are soluble or may be fluxed with the heavier liquid members of the preceding series. Many of them, however, are insoluble in the liquid hydrocarbons of low molecular weight, particularly those of the paraffin series. This fact is made the basis of the determination of asphaltenes in petroleums and asphalts (see Art. 45).

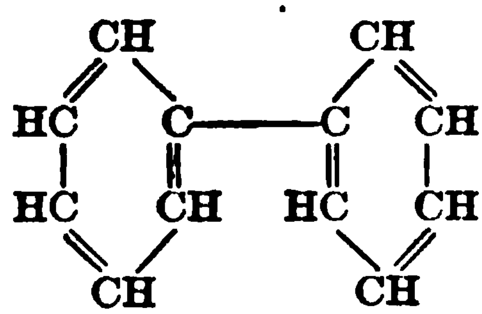
The Benzene Series of hydrocarbons have a structure analogous to that of the hexamethylenes or naphthenes. They are monocyclic, and the cycle, known as the benzene nucleus, contains six carbon atoms. Three double valences occur between adjacent carbon atoms so that the cycle is unsaturated. The general molecular formula for all members of this series is C_nH_{2n-6}. The common difference CH_2 exists between adjacent members. The first member is benzene C_6H_6. Its graphic formula, together with those of the next two members, is as follows:



Benzene C_6H_6 Toluene C_7H_8 Xylene C_8H_{10}

From the third member up isomers occur, there being four isomeric forms of xylene. Benzene may be considered as the product produced by the polymerization of three acetylene molecules in which the triple valences break down to double valences. It is also directly related to the naphthene series. By breaking down the double valences to single, and satisfying the free valences thus produced by hydrogen, the benzene becomes hydrogenized to hexahydrobenzene or hexamethylene. The nomenclature of the members of the naphthene series is thus established. A benzene molecule from which one hydrogen atom has been removed gives a monovalent radical called phenyl. While the benzene hydrocarbons are less stable chemically than the paraffins and naphthenes, the benzene nucleus does not readily break down. All of the series react with fuming sulphuric acid to form sulphonic acids in which the benzene nucleus is preserved. The lighter members of the benzene series are liquids and the higher members are solids at ordinary temperature. They are mutually soluble in one another and the lighter liquids are excellent solvents for most of the solid hydrocarbons of other series. This series occurs to a marked extent in tars. It is one of a number of series, known as aromatic hydrocarbons, which predominate in tars and give to them certain peculiar characteristics.

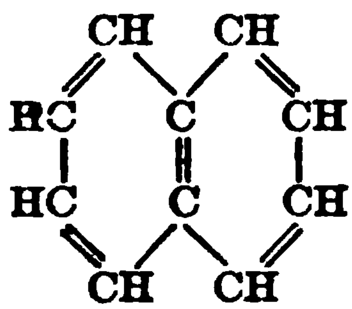
The Polyphenyl Series embrace a number of series of hydrocarbons whose members contain two or more phenyl radicals or benzene nuclei connected by single valences. The general formulas for these series are C_nH_{2n-14}, C_nH_{2n-16}, C_nH_{2n-18}, etc. The simplest type of hydrocarbon in the polyphenyl series is diphenyl, which is the first member of the dicyclic series or diphenyl series. Its graphic formula, which has its analogue in the dicyclic polymethylenes, is as follows:



Diphenyl
$C_{12}H_{10}$

The polyphenyls are normal constituents of tars but are of less importance than other polycyclic aromatic hydrocarbons, such as the naphthalene and anthracene series.

The Naphthalene Series of hydrocarbons contain a condensed nucleus composed of two benzene nuclei having two carbon atoms in common. Its general formula is C_nH_{2n-12}. Naphthalene, $C_{10}H_8$, is the first member of this series. Its graphic formula is as follows:

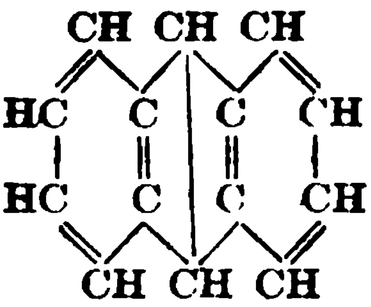


Naphthalene CH_{810}

Naphthalene itself deserves especial consideration because, of any single hydrocarbon, it probably occurs to the greatest extent in tars which are of interest in highway engineering. It is a white crystalline body which melts at 79° C (174° F) and boils at 218° C (425° F), but volatilizes readily at ordinary temperature. Altho solid, it is a powerful solvent or flux for the solid hydrocarbons of other series present in tars. The members of the naphthalene series are acted upon by concentrated sulphuric acid.

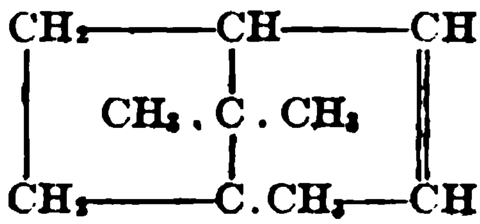
The Anthracene Series of hydrocarbons have a rather complicated condensed nucleus consisting of two unaltered and one altered benzene cycles, two carbon atoms being common to adjacent cycles. The general formula of this series is C_nH_{2n-18} and the graphic formula for its first member,

anthracene, is as given below: The members of the anthracene series are solids which occur mainly in tars. They are mutually soluble in members of the benzene and naphthalene series and are acted upon by concentrated sulphuric acid.



Anthracene $C_{14}H_{10}$

Other Unsaturated Cyclic Series. There are a number of other unsaturated cyclic series whose members occur in various bituminous materials. Many of them are solids which in mixture or solution with other fluid hydrocarbons impart cementitiousness to the mass. Some of them are of very complicated structure but are usually related in some way to the hexamethylene or benzene nuclei. As an example of this class may be mentioned camphene, whose graphic formula is as follows:



Camphene $C_{10}H_{16}$

This compound belongs to a group of hydrocarbons known as turpenes, which are present to a marked extent in resinous or rosinlike bodies. Members of the turpene group have been found in bituminous materials which possess cementitious qualities.

4. Interrelationship of Hydrocarbons

Relations Existing Between Members of the Same Series. Certain general relations exist between different members of any given series of hydrocarbons which are as a rule quite similar to the relations existing between members of any other series. The following rules are generally true for the normal members of a given hydrocarbon series, but the isomers sometimes create exceptions. (1) Members of a given series are usually completely soluble in one another. (2) As the number of carbon atoms in the molecule or the molecular weight increases, the specific gravity usually increases. (3) As the molecular weight increases, the coefficient of expansion decreases. (4) As the molecular weight increases, the liquefying temperatures of the gaseous hydrocarbons rise. (5) As the molecular weight increases, the boiling points of the liquid hydrocarbons become higher. (6) As the molecular weight increases, the melting points of the solid hydrocarbons become higher. (7) All members of a given series possess certain properties in common by which the series to which they belong may be identified. These relations greatly influence the relations between different grades of the same type of bituminous material as given under individual tests. See Arts. 32 to 48 inc.

Relations Existing Between Different Series. The interrelationship of certain hydrocarbon series has been shown to some extent in Arts. 1 and 2. All of the series are related to one another either directly or indirectly, and this fact has a most important bearing upon the production and manufacture of bituminous materials. These relations should be clearly understood in order to appreciate the similarities and differences existing in bituminous materials of different types and also the modifying effects produced by the various processes of manufacture and methods of manipulation. All hydrocarbons are composed of the same elements. The innumerable compounds, each possessing its own individual and peculiar characteristics, are merely the result of different structural combinations of hydrogen and carbon atoms in varying proportions and quantities. By breaking up the various structures and recombining the atoms or radicals

new compounds are formed. Thus members of one series under favorable conditions are transformed into members of other series. Paraffins may be broken down to olefines under suitable conditions of temperature and pressure. Olefines may polymerize to naphthenes and acetylenes to benzenes. Benzenes may be hydrogenized to naphthenes or condensed to naphthalenes and anthracenes. Naphthenes may be converted into polycyclic polymethylenes and benzenes and naphthenes may in turn produce turpenes. It is for these reasons that nature starting with the same identical raw material may produce in one case paraffin petroleum and in another asphaltic petroleum or asphalt. These are the reasons why, by artificial processes, two such unlike materials as bituminous coal and petroleum may be made to yield tars quite similar in character, and why certain petroleums may be made to yield asphalts. Comparatively little has been published upon the general interrelationship of bituminous materials from the standpoint of hydrocarbon chemistry. A great deal of information regarding members of the different series is, however, to be found in textbooks on organic chemistry.

CLASSIFICATION

5. Methods of Classification

Nomenclature. The nomenclature of bituminous materials is introduced at this point in order that the general relationship of materials and their properties may be understood and in order that the definitions may be readily accessible for consultation during the perusal of this Section. The following terms are arranged in groups according to a logical sequence rather than alphabetically. Those marked with an * have been adopted as standard by the American Society for Testing Materials; those marked with a ‡ have been recommended to the American Society for Testing Materials by the Committee on "Standard Tests for Road Materials"; and those marked with a † have been proposed to the American Society of Civil Engineers by the Special Committee on "Materials for Road Construction and Standards for Their Test and Use."

General Definitions

Bitumen.*† A mixture of native or pyrogenous hydrocarbons and their non-metallic derivatives, which may be gases, liquids, viscous liquids, or solids, and which are soluble in carbon disulphide.

Bituminous.* Containing bitumen or constituting the source of bitumen.

Bituminous Material.† Material containing bitumen as an essential constituent.

Liquid Bituminous Material.* One having a penetration at 25° C (77° F), under a load of 50 g applied for 1 sec, of more than 350.

Semisolid Bituminous Material.* One having a penetration at 25° C (77° F), under a load of 100 g applied for 5 sec, of more than 10, and a penetration at 25° C (77° F), under a load of 50 g, applied for 1 sec, of not more than 350.

Solid Bituminous Material.* One having a penetration at 25° C (77° F), under a load of 100 g applied for 5 sec, of not more than 10.

Bituminous Emulsion.‡ A liquid mixture in which minute globules of bitumen are held in suspension in water or a watery solution.

Flux.*† Bitumen, generally liquid, used in combination with a harder bitumen for the purpose of softening the latter.

Cut-Back Product.* Petroleum or tar residuum which has been fluxed with a distillate.

Petroleums

Petroleum.‡ Liquid bitumen, occurring as such in nature.

Topped Petroleum.‡ Petroleum deprived of its more volatile constituents.

Blown Petroleum.*† A semisolid or solid product produced primarily by the action of air upon a liquid native bitumen which is heated during the blowing process.

Asphalts

Asphalt.*† Solid or semisolid native bitumen, solid or semisolid bitumen obtained by refining petroleum, or solid or semisolid bitumen which is a combination of the bitumens mentioned with petroleums or derivatives thereof, which melts upon the application of heat and which consists of a mixture of hydrocarbons and their derivatives of complex structure, largely cyclic and bridge compounds.

Native Asphalt.* Asphalt occurring as such in nature.

Asphalt Cement.* A fluxed or unfluxed asphalt especially prepared as to quality and consistency for direct use in the manufacture of bituminous pavements, and having a penetration at 25° C (77° F) of between 5 and 250, under a load of 100 g applied for 5 sec.

Rock Asphalt.‡† Sandstone or limestone naturally impregnated with asphalt.

Tars

Tar.*† Bitumen which yields pitch upon fractional distillation and which is produced as a distillate by the destructive distillation of bitumen, pyrobitumen or other organic material.

Dehydrated Tar.*† Tar from which all water has been removed.

Refined Tar.*† Tar freed from water by evaporation or distillation until the residue is of desired consistency; or a product produced by fluxing tar residuum with tar distillate.

Coal Tar.*† The mixture of hydrocarbon distillates, mostly unsaturated ring compounds, produced in the destructive distillation of coal.

Gas-House Coal Tar.*† Coal tar produced in gas-house retorts in the manufacture of illuminating gas from bituminous coal.

Coke-Oven Tar.*† Coal tar produced in by-product coke ovens in the manufacture of coke from bituminous coal.

Oil-Gas Tar.*† Tar produced by cracking oil vapors at high temperatures in the manufacture of oil gas.

Water-Gas Tar.*† Tar produced by cracking oil vapors at high temperatures in the manufacture of carbureted water-gas.

Pitch.*† A solid residue produced in the evaporation or distillation of bitumen, the term being usually applied to residues obtained from tars.

Straight-Run Pitch.* A pitch run to the consistency desired, in the initial process of distillation, without subsequent fluxing.

Dead Oil.*† Oil with a density greater than water, which is distilled from tar.

Definitions Relating to Tests

Asphaltenes.*† The components of the bitumen in petroleum, petroleum product, maltha, asphalt cement, and solid native bitumen, which is soluble in carbon disulphide but insoluble in paraffin naphtha.

Carbenes.*† The components of the bitumen in petroleum, petroleum product, maltha, asphalt cement, and solid native bitumen, which is soluble in carbon disulphide but insoluble in carbon tetrachloride.

Free Carbon in Tar.*† Organic matter which is insoluble in carbon disulphide.

Fixed Carbon.*† The organic matter of the residual coke obtained upon burning hydrocarbon products in a covered vessel in the absence of free oxygen.

Normal Temperature.*† As applied to laboratory observations of the physical characteristics of bituminous materials, is 25° C (77° F).

Consistency.*† The degree of solidity or fluidity of bituminous materials.

Viscosity.‡† The measure of the resistance to flow of a bituminous material, usually stated as the time of flow of a given amount of the material thru a given orifice.

Penetration.‡ The consistency of a bituminous material expressed as the distance that a standard needle vertically penetrates a sample of the material under known conditions of loading, time and temperature. When the conditions of test are not specifically mentioned, the load, time and temperature are understood to be 100 g, 5 sec, 25° C (77° F), and the units of penetration to indicate hundredths of a centimeter.

Main Divisions. As the term bituminous is used not only in connection with materials consisting of or containing bitumen, but also with materials constituting the source of bitumen, two main divisions of bituminous materials are thus established. The two divisions are distinguished by the fact that members of the former are either wholly or to a considerable extent soluble in carbon disulphide, while members of the latter are not.

Materials Consisting of or Containing Bitumen may, from the standpoint of highway engineering, be divided into two groups: (1) Petroleum and asphalt products; (2) tar products. They may also be classified according to the use for which they are best suited, such as dust palliatives, carpet or mat building materials, and materials incorporated in the wearing course proper during construction. The most logical method, however, is to classify them under the headings: (1) Native bitumens and bituminous materials, and (2) artificial and refined bitumens and bituminous materials. This method has been followed in Arts. 6 and 7.

Materials Constituting the Source of Bitumens and Bituminous Materials vary greatly in character. The term bituminous is not customarily applied to all of these materials but mainly to that class of substances known as pyrobitumens. Thus wood, if destructively distilled, is the source of certain bitumens, but it is not ordinarily termed a bituminous material. On the other hand, coal, which, if destructively distilled, will produce bitumens, is termed bituminous coal. Bituminous coal is a pyrobitumen and from the standpoint of highway engineering is the only one of any great importance. It is therefore unnecessary to further classify the pyrobitumens except to state that they are produced in nature either by the direct metamorphosis of vegetable matter or else by the action of heat upon the bitumens themselves. In the latter case they are called indurated bitumens or asphaltic coals.

6. Native Bitumens and Bituminous Materials

Classes. The native bitumens and bituminous materials divide themselves according to their physical state into three main classes: gases,

liquids, and solids. No absolutely sharp distinction can be made between the liquids and solids because of an intermediate class known as semisolids, which gradually merge from the extremely viscous liquids to the harder solids. It is, however, customary to consider most of the semisolids with the solids. This method has been adopted in the following classification. In this classification certain materials which are only indirectly of interest in highway engineering have been included. Those which are of most importance are considered in detail in subsequent articles.

Gases. The two native hydrocarbon gases of interest are:

1. Marsh gas, mostly methane, formed by the decomposition of vegetable matter under water;

2. Natural gas, mostly C_nH_{2n+2} hydrocarbons, formed under similar conditions to petroleum and often accompanying it.

Fluids. The fluid native bituminous materials embrace the petroleums and malthas. The petroleums run from thin fluids to those which are very viscous and almost semisolid. There are two well-defined classes of petroleums, paraffin and asphaltic. There is also an intermediate class commonly termed semiasphaltic. In the following classification the malthas are included under the extremely viscous asphaltic and semiasphaltic petroleums:

1. Paraffin petroleums, consisting principally of C_nH_{2n+2} hydrocarbons, which series predominates among the solid hydrocarbons held in solution;

2. Asphaltic petroleums, consisting principally of cyclic hydrocarbons of the C_nH_{2n}, C_nH_{2n-2}, C_nH_{2n-4}, etc, series. The unsaturated polycyclic series predominate among the solid hydrocarbons held in solution to the practical exclusion of paraffin hydrocarbons. When these petroleums are very viscous and are found impregnating porous rock to the extent of not over 25%, the entire mass of bituminous rock is often called rock asphalt;

3. Semiasphaltic petroleums containing a considerable proportion of fluid and some solid C_nH_{2n+2} hydrocarbons; but also carrying a large amount of cyclic C_nH_{2n}, C_nH_{2n-2}, C_nH_{2n-4}, etc, hydrocarbons, the unsaturated polycyclic series predominating among the solid bodies held in solution.

Solids. The solid native bituminous materials divide themselves into two main classes, paraffin and asphaltic. The latter only are of importance from the standpoint of highway engineering.

1. Paraffin bodies with distinctive names such as ozocerite and hatchettite, consisting mainly of C_nH_{2n+2} hydrocarbons, probably produced in nature from paraffin petroleums.

2. Asphaltic bodies consisting almost entirely of cyclic hydrocarbons of the C_nH_{2n}, C_nH_{2n-2}, C_nH_{2n-4}, etc, series. These substances range from semisolids to hard brittle black minerals somewhat resembling coal in appearance. The unsaturated polycyclic hydrocarbons predominate but vary considerably in their relative proportions. Many of them carry high percentages of mineral matter, and when this is in excess of the bitumen they are often termed rock asphalts. The solid asphaltic bitumens are soluble in or may be fluxed with the liquid bitumens. They have probably been produced in nature from asphaltic petroleums and with some few exceptions are called asphalts. Some of them have distinctive mineralogical names such as gilsonite and grahamite.

7. Artificial and Refined Bitumens and Bituminous Materials

Groups. The artificial and refined bitumens and bituminous materials of direct interest in highway engineering can be most conveniently grouped and classified according to their derivation and method of production. Of the following divisions, group A consists of crude artificial bitumens whose refined products are covered by group C. Group B covers refined products of the fluid native bitumens, group D of the solid native bitumens, and group E covers refined mixtures of members of group A with the native products. Group F covers bituminous emulsions.

A. Materials Derived from the Destructive Distillation of Bitumens and Pyrobitumens which consist of a mixture of liquid hydrocarbons are called tars. Those of most importance are as follows:

1. **Water-gas tars** produced from petroleums or petroleum products in the carburation of water-gas, which are thin liquids consisting mainly of unsaturated cyclic hydrocarbons of the C_nH_{2n-6}, C_nH_{2n-12}, C_nH_{2n-18}, and similar series.

2. Coal tars produced in the manufacture of gas or coke from bituminous coal, usually viscous liquids consisting mainly of hydrocarbons of the C_nH_{2n-6}, C_nH_{2n-12}, C_nH_{2n-18}, and similar series together with their oxygen and nitrogen derivatives.

B. Materials Derived Primarily from the Fractional Distillation of Fluid Native Bitumens include the following refined products:

1. Petroleum distillates which are thin fluids.
2. Petroleum residues which may be
   Fluid residual oils,
   Asphalt cements,
   Refined asphalts.

C. Materials Derived Primarily from the Fractional Distillation of Tars include the following products:

1. Tar distillates which are thin fluids.
2. Tar residues which may be
   Fluid refined tars,
   Semisolid refined tars,
   Tar pitches.

D. Materials Derived Primarily by Refining and Fluxing Solid Native Bitumens and Bituminous Materials include the following:

1. Refined native asphalts.
2. Asphalt cements.

E. Mixtures of Tar and Petroleum or Asphalt Products are known as tar-asphalt compounds and usually vary from fluid to semisolid consistency.

F. Bituminous Emulsions are mixtures of bitumens with soap solutions, the resulting products thus being made readily miscible with water. They include:

1. Petroleum emulsions.
2. Asphalt emulsions.
3. Tar emulsions.

8. Classification According to Purpose for Which Used

Uses in Highway Engineering. Bituminous materials are used in a variety of ways in the treatment and construction of highways, the more important being as dust palliatives, in the construction of bituminous

mats or carpets, in the highway structure proper, as fillers, as fluxes and as impregnating materials. In the following classification are given those materials which are ordinarily used for the purposes above mentioned:

Dust Palliatives include crude fluid petroleums, heavy petroleum distillates, topped or partially distilled petroleums, petroleum emulsions, crude tars, partially dehydrated tars, fluid refined tars and tar emulsions.

Materials for Surface Mats or Carpets include viscous fluid residual petroleums, fluid cut-back asphalts, asphalt emulsions, viscous refined tars and viscous tar-asphalt mixtures.

Matérials for Incorporation During Construction include cut-back asphalts, asphalt cements, asphalt emulsions, very viscous refined tars, soft tar pitches and very viscous tar-asphalt mixtures.

Fillers include certain types of asphalt cements and tar pitches.

Fluxes include petroleum distillates (cutting-back fluxes) and viscous fluid residual petroleums.

Impregnating Materials for Wood Block include heavy tar distillates (creosoting oils) and mixtures of tars with tar distillates.

REFINING PROCESSES

9. Removal of Non-Bituminous Impurities

Sedimentation. With few exceptions crude bituminous materials, both native and artificial, contain impurities of a non-bituminous nature. In the crude state they are seldom adaptable for direct use in highway engineering and are usually subjected to purification and refining processes. Water is the most common impurity in both fluid and solid bituminous materials. Mineral matter, vegetable matter and occluded gases are other naturally occurring impurities. As most of these impurities are not soluble in the bitumen proper and as they differ from the bitumen in specific gravity, they may be removed wholly or in part by the process of sedimentation or separation by gravity. In the more fluid bituminous materials natural sedimentation occurs during storage. In the viscous fluids and solids heat is required to make the bitumen sufficiently liquid to allow the separation to take place. Water and mineral matter are the common impurities of petroleums. Upon standing in large storage tanks both settle to the bottom, leaving the practically pure bitumen above. The mineral matter consists of silt and sand called bottom settlings or B. S. Very viscous petroleums persistently retain a small amount of water which may be removed during the early stages of distillation if it is to be distilled. In many cases it is more expeditious to remove it by topping the oil, in what is known as a topping plant, before charging it into the still. In some cases storage tanks are fitted with steam coils by means of which the oil is warmed to a state of fluidity which facilitates the settlement of impurities. Water and free carbon are the common impurities of crude tars. The water may to a great extent be removed during storage, in which case it rises to the surface owing to the heavier gravity of the tar bitumen. The free carbon permeates the tar in a very finely divided state and can not well be removed except by filtration under pressure. This is seldom resorted to. The free carbon therefore appears in the refined tar. A small amount of water almost invariably remains in the tar and this may be removed during distillation or by a special dehydrating treatment previous to distillation. Solid native bitumens, if they contain impurities, have to be heated to a rather high temperature before they become sufficiently

fluid to separate from these impurities. In order to prevent local overheating they are usually agitated. Water and gases are driven off during the process. Some mineral matter settles out and the larger fragments of vegetable matter rise to the surface and are skimmed off. The mineral matter is sometimes so finely divided that it will not readily settle out and agitation further hinders separation. Both finely divided mineral matter and vegetable matter therefore commonly occur in the refined asphalt, altho to a lesser extent than in the crude.

Dehydration. Dehydrating processes are designed primarily for the removal of water in bituminous materials which will not completely separate water by sedimentation. It is desirable to do this prior to distillation because of the fact that the presence of water creates a tendency to foam when the mass of bituminous material is heated to about the temperature of boiling water. This makes it a troublesome and expensive procedure to remove water by distillation. Many dehydrating devices have been invented for use with petroleums and tars. The one in most common use for petroleum is known as a topping plant. In this device the oil is pumped under pressure thru a length of pipe containing a great many abrupt bends so that the path of the oil is exceedingly devious. The pipe work is set in a furnace so that it may be suitably heated. As the oil under pressure passes thru this pipe it is heated to a temperature above that of boiling water. This pipe discharges in a spray thru a loaded valve into a large expansion chamber where the water and more volatile constituents separate in the form of vapor which is condensed in a coil for the recovery of the light hydrocarbons. The hot oil passes thru another pipe direct to the still or storage tank. One of the most successful methods for dehydrating viscous tars is to cause the tar to flow in thin films over heated baffle-plates placed in an air-tight chamber to which vacuum is applied. Here the water and more volatile constituents volatilize without causing the tar to foam dangerously and the volatile products are then carried thru a condensing system where the light oils condense and separate by gravity from the condensed water. The dehydrated tar passes out thru another opening to the still or storage tank.

10. Distillation

Fractional Distillation is that form of distillation in which the original constituents of a mixture are separated mechanically and without chemical change. When a large number of compounds are present in a liquid mixture or in solution and the boiling points of many of these compounds are quite close together, it is impossible to separate the individual constituents, even qualitatively, by a single distillation. This is due to the fact that a relatively small quantity of the higher boiling constituents is mechanically carried over with the vapor of the low boiling constituents and in like manner a relatively small quantity of the lower boiling constituents is mechanically entangled and held back by the higher boiling constituents. If, however, fractions of the distillate are made within comparatively narrow temperature limits, as indicated by the temperature of the vapor emerging from the still, cuts will be obtained which carry a preponderance of those constituents whose true boiling points come within the limits observed. A refractionation of the individual cuts will then result in a further and more complete separation of the constituents. Petroleums and tars are usually subjected to fractional distillation in the manufacture of bituminous materials of interest in highway engineering. As both are

mixtures or solutions of a great many hydrocarbons, no attempt is made to recover individual constituents by a single distillation. The distillation is usually made upon the crude product which has been partially separated from its impurities by sedimentation or dehydration. All distillation operations involve apparatus or equipment consisting of at least three basic units: (1) A still or receptacle in which the material is heated; (2) a condenser in which the vapors coming from the still are condensed; (3) a receiver in which the condensed products are caught. In the distillation of petroleums and tars two main classes of products are obtained: (1) Distillates which pass over into the receiver; and (2) residues which remain in the still. The former, with a few exceptions, are of comparatively little interest from the standpoint of highway engineering. The residues, however, often constitute the materials directly used in the treatment or construction of highways. These residues vary in character and usefulness, to a very great extent depending upon the main object of the manufacturer in making the distillation. If he is working primarily for distillates the character and quality of the residues for highway purposes are often greatly impaired and sometimes ruined (see Art. 10, CRACKING). The shape and size of stills used in refining petroleums and tars vary to a considerable extent but they are usually cylindrical and are either partially or wholly bricked in. More detailed descriptions will be found in Arts. 19 and 28. Many of the heavier hydrocarbons suffer chemical change at temperatures lower than their boiling point. They can not therefore be fractionally distilled without breaking down into new compounds, unless means are devised to remove them at a lower temperature. In the manufacture of bituminous materials for highway work it is often necessary to remove certain of these compounds from the residues without allowing them to break down into other less desirable hydrocarbons, some of which would remain in the still. There are two methods of securing the desired results: (1) Distillation under reduced pressure, known as vacuum distillation; (2) distillation with live steam. In the former the normal boiling points of all of the hydrocarbons are lowered under the reduced pressure to such an extent that many of those which would otherwise break down before vaporizing pass over readily into the distillate at the lower temperature. In the distillation with steam, which is more commonly employed, the heavier hydrocarbons are mechanically carried over into the distillate in large quantities at temperatures much lower than their normal boiling points by the large volume of steam that is continuously injected into the liquid mass during distillation. The use of steam of course results, for the same reason, in cuts or distillate fractions, whose constituents show a wider range of boiling points. In the distillation of tars air is often used in place of steam. The oxygen of the air reacts to some extent with the hydrocarbons present so that the resulting distillation cannot be said to be strictly fractional. This action is, however, extremely slight in comparison with that produced by the action of air upon petroleums during distillation (see Art. 11, BLOWING). In the fractional distillation of petroleums and tars the cuts in the distillates may be made either according to the temperature as registered by a thermometer placed in the vapor before leaving the still or according to the gravity of the distillate as it comes from the condenser. The latter method is that ordinarily used. At just what points cuts are made depends upon how the manufacturer intends to dispose of his distillates and what refined products he wishes to make of them. Many distillates are further refined by refractionating them and subjecting them to chemical purification (see

Art. 10, TREATMENT OF DISTILLATES). Some water usually accompanies the low boiling and light gravity distillates unless the original material has previously been very thoroly dehydrated. This water readily separates by gravity from the hydrocarbon distillate, which is considerably lighter. In the case of steam distillation, water also accompanies the heavier and higher boiling hydrocarbon distillates. As distillation progresses the specific gravity of the distillate becomes greater. Petroleum distillates are, however, always lighter than water, no matter how far the fractional distillation is continued. On the other hand the heavier tar distillates weigh considerably more than water. The residue remaining in the still, while always fluid at the distilling temperature, if cooled to normal temperature will be found to become more and more viscous and as distillation progresses to pass thru the semisolid to solid state. When highway materials are being primarily produced samples of the residue are withdrawn from time to time, cooled and tested for consistency. The distillation is stopped when the desired consistency has been obtained. Owing to the fact that the large mass of material in the still retains its heat for a long time, a certain amount of distillation continues even after the fires have been drawn. This makes it necessary to draw the fire some time before the desired consistency of the refined product has been reached. Experience soon demonstrates just when to draw the fire for the production of a desired product from any given material.

Cracking. The term cracking is used to designate the process of splitting up a hydrocarbon or hydrocarbons into other hydrocarbons by the action of heat. The cracking of any given hydrocarbon usually results in the formation of at least one other hydrocarbon which carries a higher percentage of carbon than did the original, and therefore at least one which carries a lower percentage of carbon and a higher percentage of hydrogen. If cracking occurs during fractional distillation, this results in the production of a distillate of lower gravity and boiling point than that which would have been produced had the operation been purely fractional. In addition, it almost invariably results in the formation of hydrocarbons more unsaturated than the original hydrocarbon which is cracked. This has a most important bearing upon the character of both distillate and residue as compared with those obtained from the same material by purely fractional distillation. Many hydrocarbons crack at a temperature lower than their boiling points and many of those which normally boil and distil unaltered will crack if suddenly subjected to a temperature higher than their normal boiling point. Distillation of petroleums and tars under reduced pressure or with live steam agitation materially reduces but does not entirely prevent cracking, so that absolute fractional distillation is seldom attained. Distillation of the heavier hydrocarbons at normal pressure and without agitation promotes cracking, and if carried on under increased pressure cracking is greatly increased. It may also be increased to a marked extent by causing condensation of the vapors within the still itself whereby the condensed hydrocarbons fall back upon the residual mass which is at a considerably higher temperature than their boiling points. This may be accomplished by exposing the upper part of the still in such manner that it is considerably cooler than the lower portion. Banking the fire under a still during distillation also produces a similar effect. Unless agitation of some sort is utilized during distillation that portion of the material in contact with the still bottom will become overheated to such an extent that cracking and even coking will be induced. This is

not only true of distillation but also of any other heating process where direct fire or very hot gases are the source of heat. As the very low boiling, low gravity distillates are often the most valuable and as the percentage obtainable from a given bituminous material may often be materially increased by cracking, such process may be purposely employed by a manufacturer who is working primarily for distillates. On the other hand, if a desirable residue is the principal product to be manufactured, cracking is studiously avoided (see Art. 10, FRACTIONAL DISTILLATION), and extraordinary methods are employed to reduce it to a minimum. This is due to the fact that cracked residuums are extremely unstable and it is almost impossible to accurately control their consistency and other physical properties.

Destructive Distillation is that in which a material is distilled until only coke remains as a residue in the still. In the refining of petroleums and tars this process is only employed when it is desired to obtain the maximum quantity of distillate and the production of a bituminous residuum is not required. As applied to bituminous materials it is of interest only in connection with the formation of tars, or distillates which upon being fractionally distilled will yield pitches. From this standpoint it is considered in detail under Art. 25.

Treatment of Distillates. Petroleum and tar distillates used in highway engineering are not ordinarily subjected to further refining processes after they have once been collected except in the case of some petroleum distillates which are chilled and filtered to extract the more valuable solid paraffins. Those which are not directly of interest in highway work are, however, often further refined by refractionation and treatment with concentrated sulphuric acid. The acid treatment is used to remove the undesirable unsaturated hydrocarbons which usually contain an unsaturated open chain. These hydrocarbons react with the acid to form sulphonic acids which are practically insoluble in the distillate itself and which because of their higher gravity separate readily from the distillate. Sulphuric acid also precipitates certain heavier hydrocarbons which are believed to be held in colloidal solution and in addition promotes the polymerization of certain hydrocarbons to compounds somewhat similar to those left in the residuum from the original distillation. The acid treatment is made in a cylindrical lead-lined agitator with a conical bottom into which the heavier sulphonic acids settle. Agitation or diffusion of the acid thruout the body of distillate is usually secured by means of an air blast injected at the bottom of the agitator. After treatment the sludge acid is withdrawn and diluted with water, which breaks up the sulphonic compounds and sets free the hydrocarbons which had combined with the acid. These hydrocarbons separate by gravity from the diluted acid and are sometimes recovered, in which case they are known as acid sludge. Sometimes this acid sludge, which still contains some acid, is semisolid. The acid may be neutralized and removed by the action of a solution of caustic soda and the sludge then distilled. The residual acid sludges then resemble in some respects the residuums obtainable from the material originally distilled. These sludge residuums from petroleum distillates are of interest as having been used in some instances as a material of highway engineering.

11. Oxidation

Sulphurizing. If, during distillation of a petroleum, sulphur is thrown into the still, hydrogen sulphide gas, H_2S, is copiously evolved and a much

greater percentage of residuum of a given consistency is produced than could have been obtained by straight distillation. This is due to the removal of hydrogen from certain hydrocarbon molecules, thus producing radicals which unite to form much heavier and less volatile hydrocarbons. The residuums thus produced vary in certain characteristics from residuums of the same consistency produced by fractional distillation. In addition to the removal of hydrogen, which is known as an oxidizing reaction, the sulphur may also react with some of the hydrocarbons to form sulphur derivatives, or hydrocarbon molecules which contain sulphur. The former reaction is, however, the more important. The sulphurizing process was at one time quite extensively used but has been largely abandoned since it has been found that blowing air thru heated petroleum produces much the same results.

Blowing. In the blowing process air is forced thru the hot petroleum so as to cause violent agitation. The oxygen of the air then removes hydrogen from certain hydrocarbon molecules and forms water which passes off in the form of vapor. Like sulphur it may also combine to a slight extent with certain hydrocarbons to form hydrocarbon derivatives containing oxygen. As a rule the blowing process is conducted only upon viscous or semisolid petroleum residuums. It results in increasing the consistency of the residuum without material loss in weight or change in gravity. The reaction proceeds most vigorously at a temperature of over 205° C (400° F) and the heat of the reaction is then of sufficient magnitude to maintain the residuum in a fluid state without the application of external heat. Considerable care is required to keep the residuum at a temperature lower than its flash point, or otherwise the injection of copious quantities of air is apt to cause spontaneous combustion. The formation and distinguishing characteristics of blown petroleums are given in Art. 20.

12. Fluxing

Fluxing with Residuals. The solid native bituminous materials are usually too hard to be used directly in highway engineering. After preliminary refining, consisting of the partial or complete removal of impurities, they are softened to the desired consistency by combining or fluxing them with fluid or relatively soft petroleum residuums. Solid petroleum residuums may also be softened in the same manner. The fluxing process is ordinarily conducted in an open tank or kettle which may be equipped with steam coils or heated direct. The hard residuum is first melted in the kettle, after which a sufficient amount of the heated petroleum residuum or flux is run in so as to produce a finished product of desired consistency. Rather prolonged agitation of the contents of the kettle is required to secure an absolutely uniform product. Such agitation may be obtained by means of a mechanical stirring device, or by agitation with steam or air. Mechanical agitation is preferable in certain respects but is not as efficient as the other two methods. Agitation with steam is desirable from many standpoints but invariably results in the mechanical removal of some of the lighter constituents present. Air agitation on the other hand causes some oxidation to take place, altho the temperatures employed are not as high as that at which such oxidation becomes very pronounced. In both steam and air agitation, however, some allowance, in the proportion of flux to be used, should be made for unavoidable hardening. In general the proportion of flux used is considerably less than for the material fluxed. In some

cases, however, a large proportion of soft blown petroleum residuum may be hardened or reinforced to the desired consistency by incorporating with it a relatively small amount of a harder bituminous material.

Fluxing with Distillates. Distillates are sometimes used as fluxes for the harder bituminous materials, which are then said to be cut-back. The term cutting-back was originally applied to the practice of first distilling a bituminous material until the residuum was hard and brittle in order to obtain certain valuable products from the heavier distillates, after which a portion of the distillate was run back or incorporated with the hard residuum to bring it to the desired consistency. It has, however, gradually come to be used to denote the use of a distillate as a flux for any natural or artificial residuum.

Emulsification. All bitumens are practically insoluble in water. By mechanical agitation some of them may be temporarily emulsified with water, all but a small portion of which soon separates by gravity. If, however, a strong solution of soap is used the soap acts as a medium for holding the bitumen and water together in suspension or emulsion and, if properly made, such emulsion may be further mixed or diluted with water without causing separation. Dilute bituminous emulsions are nevertheless in a delicate state of equilibrium and often ready to separate upon slight provocation. Emulsions of petroleums, asphalts and tars may be obtained under suitable conditions. Sometimes instead of using a manufactured soap, manufacturers of bituminous emulsions first combine the bitumen with an animal or vegetable oil or fat and then saponify the mixture by means of caustic soda, potash or ammonia.

PETROLEUMS

13. Origin of Petroleums

Occurrence of Petroleums. Petroleums are fluid native bitumens widely distributed over the earth. They are known as mineral oils in contradistinction to those occurring in animal and vegetable matter. Their name is derived from the Latin words " petra," rock, and " oleum," oil, and they are usually found within rock formations. History records a knowledge of their occurrence as early as 450 B.C. at Kirab, Persia. Altho they originally occur in rock formations, their seepage to the surface of the earth thru natural rock crevices is not uncommon. They are not usually collected in paying quantities from such sources however. They are commonly found in large quantities below the earth's surface at depths varying from 50 to 4000 ft and over. They are not limited to any particular geological horizon but are found in rocks of all ages from the lower Silurian to the most recent. They are frequently accompanied by water and natural gas. They are generally obtained by boring into the rock formation in which they occur. The deposits are almost invariably under pressure, sometimes as high as 600 lb per sq in, and this pressure forces them to the surface for some time after the deposit has been struck. These deposits are termed oil wells but the petroleum does not occur as a well or subterranean lake. It usually impregnates a porous stratum of rock such as sandstone or conglomerate overlaid with shale or slate which serves as a natural seal and prevents the oil from seeping to the surface of the earth. In exceptional cases it is found in immense sandstone lenses embedded in an impervious rock. The natural requirements for its collection in quantities of commercial importance are generally believed to depend upon the

structural theory which is based upon its common occurrence in anticlinal or rock arch areas (see Art. 14, MINING OF PETROLEUM). First, there must be a porous reservoir rock such as sandstone, or otherwise the petroleum will remain more or less permanently scattered thruout crevices in the rock formation. Second, there must be an impervious stratum above the porous reservoir rock or else the natural pressure or infiltrating water will cause the oil to percolate to the surface. Third, there must be water within the porous reservoir rock which, being of higher gravity than the oil, will seek a lower level and settle into structural troughs or synclines. If water is not present the oil itself will tend to collect in synclines. Fourth, there must be an anticlinal fold in which by force of gravity the oil in separating from the water will accumulate. If there are no anticlinal folds or arches the oil will gradually percolate up the dip of inclined strata to the point of ingress of the water. There are certain modifications of the anticlinal theory, such as the arrested anticline or terrace, which have been advanced to account for the accumulation of petroleum in localities where the anticlinal structure proper is lacking. Nearly all of these theories, however, involve an impervious arch formation of one sort or another.

Formation of Petroleums. Altho petroleums are of mineral occurrence they are composed of mixtures of a great number of organic compounds consisting mainly of hydrocarbons. A number of theories have been advanced as to their origin and it is doubtful if any single theory can be made to satisfactorily explain the formation of all petroleums. The theories fall into two general classes: those which consider petroleums to be of inorganic origin, and those which consider them to be of organic origin. According to the inorganic theories the formation of hydrocarbons is explained by (1) the action of thermal waters and acids upon carbonate rocks under great pressure, and (2) the action of water upon large masses of metallic carbides, which are believed to have been formed in the interior of the earth. The second theory has received more support than the first. It is well-known that calcium carbide is decomposed by water with the liberation of the hydrocarbon gas acetylene, according to the following reaction, $CaC_2 + 2H_2O = Ca(OH)_2 + C_2H_2$. In like manner aluminum carbide reacts with water to form methane, which is a constituent of natural gas, $Al_4C_3 + 12H_2O = 4Al(OH)_3 + 3CH_4$. There are a number of carbides of iron which react with water to form hydrocarbons and these reactions may be expressed by the equation, $3Fe_mC_n + 4_mH_2O = mFe_3O_4 + C_{3n}H_{8m}$. There are reasons for believing that considerable quantities of the carbides of iron have been formed within the earth and that these carbides have in some instances reacted with water to produce the magnetic oxide of iron, Fe_3O_4, and those hydrocarbons found in petroleums. The constant deflection of the magnetic needle, as noted in the locality of certain petroleum deposits, has given support to the theory of the formation of these petroleums from carbides of iron. The organic theories account for the formation of petroleum from animal or vegetable matter enclosed in sedimentary deposits which have afterwards been converted into rock. These theories may be divided into two classes: (1) Those which consider petroleums to be the product of direct decomposition or reaction of the organic matter within the formation in which it is enclosed, and (2) those which consider petroleums as distillates produced by natural causes from the enclosed organic matter. The latter is perhaps the most plausible of any single theory and may be made to explain the many variations of petroleums obtained from different localities. The vegetable matter be-

lieved to have been responsible for the formation of petroleums is known as diatoms, a minute form of plant life. Forminifera are believed to be the minute animal organisms responsible for other petroleums. With regard to the latter it is well known that a wax-like material, cholesterol, is present in all fatty animal bodies and that, when this material is destructively distilled, certain portions of the distillate are optically active (see Art. 4, ISOMERISM). From certain petroleums distillates are obtained which for similar ranges of boiling point exhibit the same optical activity as do the distillates from cholesterol. This is considered as satisfactory evidence that such petroleums have been produced from animal matter. Both animal and vegetable matter, if subjected to distillation under high pressure, can be made to yield hydrocarbon mixtures similar to those found in petroleums. In nature it is probable that distillation was conducted in the presence of steam at the lowest possible temperature and at gradually increasing but comparatively high pressures as the overlying deposits accumulated upon those formations inclosing the organic matter being distilled. The natural conditions of temperature, pressure and time cannot be duplicated in the laboratory or factory by man, and as they are most important factors in so far as the characteristics of the ultimate products are concerned, the differences between natural and artificial bitumens are readily explained. As an example may be cited the destructive distillation of organic matter under atmospheric pressure which produces distillates known as tars and which are chemically quite distinct from distillates produced from the same materials under pressure, owing to the formation of hydrocarbons of entirely different series. In nature secondary distillations might also take place which would result in a complete change in the characteristics of the first material formed. If the secondary distillation was fractional, a solid residue might remain and thus an asphalt or rock asphalt be produced. The secondary distillate would then appear as a petroleum of quite different characteristics from the one first formed.

14. Production of Petroleums

World's Production of Crude Petroleum. Statistical information relative to the production of crude petroleum dates back to 1857, with Roumania producing 1977 bbl. In 1859 the United States started with a production of 2000 bbl, about one-half as much as was produced by Roumania during the same year. Since then the production of crude petroleum has increased with wonderful rapidity until it has become the largest and one of the most important natural industries of the world. In 1860 the United States assumed the lead of the oil producing countries, which lead it has steadily maintained. Since 1903 it has annually produced more than all of the other countries combined. At the close of 1913 its total recorded production was somewhat over three billion barrels, while that of the whole world was over five billion barrels. In 1913 its nearest competitor, Russia, produced less than one-fourth as much. The world's production by countries from 1904 to 1913, according to Day (16a), is given in Table I. As of particular interest in connection with the production of bituminous materials for highway engineering should be noted the remarkable growth in the crude petroleum industry of Mexico. Starting with the production of some 200 000 bbl in 1904, it ranked next to the last of the twelve important petroleum producing countries. By 1913 it was producing over 25 000 000 bbl and ranked third among the

important petroleum producing countries. Since 1912 Mexican petroleum has been extensively used in the manufacture of bituminous road and paving materials in the United States and promises to become a most important source of supply for European countries. Another petroleum of interest from the standpoint of highway engineering in the United States is that obtained from Trinidad, which in 1911 produced about 180 000 bbl; in 1912, 451 986 bbl; and in 1913, 503 616 bbl.

* Estimated.

Production and Importation of Petroleum in the United States. According to location and classification the oil producing areas of the United States are commonly divided into seven fields, known as (1) the Appalachian Field, (2) the Lima-Indiana or Ohio-Indiana Field, (3) The Illinois Field, (4) the Mid-Continent Field, (5) the Gulf Field, (6) the California Field and (7) the Colorado-Wyoming Field. Relatively small quantities of petroleum have also been exploited in Missouri, Michigan, Utah, Arkansas, Montana, Washington, Oregon, Idaho, Nevada, New Mexico and Alaska. The Appalachian Field extends from western New York in a

general southwesterly direction along the western side of the Alleghany Mountains, thru Pennsylvania, eastern Ohio, the northwestern part of West Virginia into eastern Kentucky and Tennessee. The Lima-Indiana Field includes the northwestern part of Ohio and middle Indiana; the Illinois Field, Illinois and northwestern Kentucky; the Mid-Continent Field, southeastern Kansas, eastern Oklahoma and northern Texas; and the Gulf Field, Louisiana and all but the northern portion of Texas. Other fields of direct interest to the United States are the Mexican and Trinidad Fields. The former covers an area embraced in the coastal plain extending along the Gulf of Mexico from the Panuco River in Tamaulipas to below Tuxpan. The latter is located on the Island of Trinidad some miles from the great lake asphalt deposits. The California, Gulf, Illinois, Mid-Continent, Mexican and Trinidad Fields produce petroleums extensively used in the manufacture of bituminous road and paving materials. The production by fields and importation of petroleum by the United States from 1904 to 1913, according to Day (16a), is given in Table II. It will be noted that the production of the Appalachian Field has quite steadily declined during the 10 years covered by Table II, and that there has been a rapid decline in that of the Lima-Indiana Field. As neither of these fields produce petroleums well adapted to the manufacture of bituminous road and paving materials, their decline is of no direct interest

in highway engineering. These petroleums, however, for many years supplied most of the demand for light distillates such as gasoline. As the demand for these distillates has increased out of proportion to the production of high gasoline bearing petroleums, many of those suitable for the manufacture of bituminous road and paving materials have been subjected to cracking processes which make them unsuitable for such use but has greatly increased the yield of light distillates. The production of California petroleums, most of which are eminently suited for the manufacture of bituminous road and paving materials, has shown a tremendous increase until in 1910 it exceeded that of Russia, the second petroleum producing country of the world. This immense increase together with the importation of large quantities of Mexican petroleum has much more than offset the marked decline in production of the Gulf Field and gradual later decline of the Illinois Field. The Mid-Continent Field, which is of some importance from the standpoint of highway engineering, has shown an increase second only to that of California. The importation of petroleum by the United States assumed considerable proportions in 1911 when over 1 700 000 bbl, almost entirely of Mexican production, were imported and used extensively in the manufacture of road and paving materials. By 1913 this importation had increased to over 17 000 000 bbl and the Mexican petroleum refining industry had become firmly established in the eastern part of the United States. During 1912 and 1913 appreciable quantities of Trinidad petroleum were imported by the United States. At the close of 1914 it was estimated that over 18 500 000 bbl of petroleum had been imported during that year, most of it coming from the Mexican Field. The estimated total production of petroleum in the United States during 1914 was 284 000 000 bbl, an increase of some 36 000 000 bbl over that of 1913.

The Mining of Petroleum. Petroleum is obtained from the porous reservoir rock in which it occurs (see Art. 13, FORMATION OF PETROLEUMS) by boring thru the overlying strata until the oil bearing rock is struck. These borings are made in much the same manner as the driving of artesian wells. In petroleum fields, the oil bearing stratum is usually struck at depths varying from 50 to 2000 ft. According to the anticlinal theory of petroleum formation, the porous stratum also contains water and may contain natural gas. As the gas, oil and water will have accumulated at different levels by force of gravity, it is necessary to locate that level at which the petroleum has collected (see Fig. 1). Once oil is found in such structural formation it is evident that a great number of borings into the same oil bearing strata will follow certain general lines. The occurrence of petroleum along these general lines was noted long before the anticlinal theory was evolved and operations were extended at both extremes of direction indicated by the general lines connecting those borings or wells which had proved most prolific. At the present time the services of trained

Fig. 1. Anticlinal Oil Bearing Stratum

geologists are employed in locating new sources of supply as their knowledge of geological formations and the probable trend and extent of oil bearing strata when once struck reduces to a science the former hit-and-miss methods of petroleum prospecting. Fig. 1 further illustrates the possible simultaneous production of gas and petroleum or petroleum and water from a single well. As the petroleum may occur under pressure, it may be driven to the surface with great force after the oil rock has been struck. Such wells are called gushers. In many cases they flow for only a few days, after which pumping becomes necessary. Certain gushers, however, flow for a long time and produce enormous quantities of oil. A possible production of as high as 200 000 bbl per day has been reported from some phenomenal gushers. The annual capacity of a single Mexican well has been estimated at 30 000 000 bbl. As the large gushers produce oil more rapidly than it can be handled, recourse is had to a process known as capping by means of which, after oil has been struck, the boring may be closed and the outflow of oil regulated by a valve. Before capping devices were perfected immense quantities of petroleum were not only lost but caused ruination to the vegetation of the localities in which the large gushers were struck. Sometimes the oil caught fire at the mouth of the well. In such a case it could not be extinguished until large quantities had been consumed in flame and the flow had greatly subsided. In many cases, after a well stops flowing and pumping proves no longer economical, an increased yield may be obtained by what is known as shooting the well. The shooting process is conducted by exploding a shell or torpedo, containing nitroglycerin, which has been lowered to the bottom of the well. The well is then said to have been torpedoed. This results in fracturing the oil bearing stratum and facilitating the flow of oil to the bottom of the boring. Frequently the flow of oil from the well is again started by this means and may continue for some time, after which pumping becomes necessary. The well may be torpedoed a number of times with good results before it is finally abandoned. Sometimes a well driven into a more favorbly located portion of the oil bearing stratum will drain oil from another well and cause it to stop producing.

Transportation and Storage of Crude Petroleum. Crude petroleum is usually transported by pipe lines and tank steamers. The pipe lines vary from 4 to 8 in in diameter and some of them are exceedingly long. They are placed well underground. Pumping stations are located at varying intervals and the oil is pumped from station to station. When the crude oil is very viscous recourse is sometimes had to a pipe rifled in much the same manner as a gun barrel. In such cases a small quantity of water is pumped with the oil and, owing to the centrifugal motion imparted by the rifling, finds its way to the inner surface of the pipe and serves as a lubricant between it and the oil. In the United States many different grades and types of petroleums are piped to the large refineries thru the same line, and the grades therefore often become mixed. The longest known line extends for a distance of 1600 miles from the Oklahoma Field northward thru Chicago and from thence to the Atlantic Coast. A refinery located at Bayonne, N. J., may therefore refine petroleum from a number of fields. When cheap water transportation can be had the crude petroleum is often piped directly to tank barges or tank steamers. In some cases where harborage is unsatisfactory the pipes are laid under water to the point at which ships may be anchored. At the Tuxpan station, Mexico, ships are loaded in the open roadstead, the oil being pumped thru submarine

pipe lines. These are connected with the ships by flexible tubing. The advantage of this method is that ships of any draught may be loaded to full capacity. Tank steamers vary somewhat in size and design but are generally divided into tanks or compartments in order that the ship may not become unbalanced when listing in a rough sea. The principal dimensions of a modern tank steamer designed to carry 2 250 000 gal of oil in bulk are as follows: Length over all 435 ft, beam 54 ft, depth 31 ft, 6 in. Such a steamer is subdivided into 16 tanks for oil. Petroleum refineries are usually so located that they may either be directly connected by pipe lines with the source of supply or else delivery from tank steamers may be made direct. At the refinery the crude oil is run into large vertical cylindrical storage tanks constructed of sheet metal and usually holding from 30 000 to 75 000 bbl. They are set rather far apart and are surrounded by an earth pit or ditch of sufficient capacity to hold the entire contents of the tank in case of leakage or fire. The greatest danger from fire is encountered from lightning during electrical storms. The pit is designed to prevent the spread of fire in such cases to other parts of the refinery by streams of burning oil. In the storage tanks sedimentation takes place (see Art. 9) and most of the water and mineral matter, if present, separates and settles to the bottom of the tank. The petroleum is piped directly from the storage tank to the topping plant or still for refining. When the contour of the site of the plant makes it practicable, the storage tanks may be set at a higher elevation than the rest of the refinery so that the oil may be run by gravity directly from the tanks to the stills.

15. Classification of Petroleums

General Characteristics. Petroleums are mixtures or solutions of a great number of hydrocarbons and often contain sulphur, nitrogen and oxygen derivatives of the hydrocarbons. In general the composition of all petroleums is similar but the relative proportions of the individual constituents vary to such an extent that wide variations occur in both the physical and chemical properties of petroleums from different sources. Upon ultimate analysis, the elemental constituents are found to occur within comparatively narrow limits for all types and grades so that the elemental composition does not serve as a practical method of classification. In general, carbon is found to lie between 80 and 87%; hydrogen 10–14%, sulphur 0–5%, nitrogen 0–2%, and oxygen 0–4%. The specific gravity of petroleum varies from 0.73 to 1.00 and slightly higher. The viscosity generally increases with the specific gravity. Petroleums vary in color from greenish brown to nearly black and often exhibit a reddish brown or orange color by transmitted light. They are sometimes slightly fluorescent. Those of lighter gravity are usually fluid, oily liquids, while the heavier petroleums are thick, viscous and often sticky. As a rule they have a rather unpleasant odor, particularly those which carry a high percentage of sulphur. They carry varying quantities of light volatile hydrocarbons which vaporize upon exposure and leave the oil more viscous, and with a somewhat higher gravity if it is subject to prolonged storage in the open. Their flash point may also be raised by this means. Many of them flash at ordinary temperature, particularly those of lighter gravity. When freed from the natural impurities such as water and sediment, petroleums are completely soluble in carbon disulphide and carbon tetrachloride, and to a large extent soluble in light gravity paraffin naphtha. As their gravity

increases, however, they become less soluble in the latter solvent. They are practically insoluble in dimethyl sulphate. When passed thru a column of fuller's earth, a fractionation of the constituents occurs and the coloring matter is removed to a great extent. This is due to what is known as selective absorption of the mineral colloidal matter, which exhibits a decided preference for the heavier black asphaltic hydrocarbons present. The first liquid percolating thru the fuller's earth is nearly water white and of very much lighter gravity than the original. Natural filtration thru clays and other colloidal matter is believed to be responsible for the formation of naphtha springs, a few of which are known to exist. The principle of selective colloidal absorption is made use of in certain refining operations to which some petroleum products are subjected. Petroleums are themselves often powerful solvents or fluxes for the asphalts and other solid native bitumens. Their solvent action in this connection increases with their gravity and usually with a decrease in their percentage of light volatile hydrocarbons. Their coefficient of expansion generally varies inversely with their specific gravity and lies between 0.0006 and 0.0009 per °C. Their specific heat also varies inversely with their specific gravity and lies between 0.4 and 0.5. There are a number of methods of classifying petroleums, the most widely used being according to locality or fields, as most of the oils from a given locality resemble each other in physical and chemical properties more closely than do those from different fields. Locality classification has to some extent been used to indicate grades, and thus the term Pennsylvania Grade has been used to cover all petroleums which exhibit properties very similar to those found in Pennsylvania, altho they may not occur in that state. Petroleums are also sometimes classified and sold according to specific gravity, particularly when oils of different gravity occur in the same field. The Baumé scale is made use of by petroleum producers and refiners in preference to direct specific gravity expressions (see Art. 33). It is therefore customary to hear a petroleum spoken of as a 38° B oil or 14° B oil, etc. The petroleums of North America in particular are often classified according to the character and quantity of semisolid residue which may be obtained by subjecting them to fractional distillation, the terms used to designate such residues or bases being paraffin, asphaltic and semiasphaltic.

Paraffin Petroleums are those in which the paraffin or C_nH_{2n+2} hydrocarbons predominate in both the fluid and solid compounds present. They are usually of low gravity and low flash point and upon fractional distillation yield large quantities of valuable light distillates, lubricating distillates and scale paraffin. The semisolid residues are soft, greasy bodies which contain a relatively small amount of the cyclic C_nH_{2n}, C_nH_{2n-2}, C_nH_{2n-4}, etc, hydrocarbons so prevalent in asphalts. They are chemically stable because of the high percentage of paraffins present. They are commercially the most valuable of any of the types of petroleums but are unsuited for the manufacture of bituminous road and paving materials except dust palliatives and fluxes, as they have practically no cementitious qualities. In the early days of the sheet asphalt paving industry, they were extensively employed in the manufacture of fluxes for refined asphalts but since the production of asphaltic and semiasphaltic petroleums has increased so enormously their use in this connection has fallen off. Petroleums from the Appalachian, Lima-Indiana Fields and some from the Mid-Continent Field are classed as paraffin petroleums. Those from the Appalachian represent the purest paraffin type and are the most valuable,

selling in certain instances as high as $2.50 per bbl at the well during 1914. A diagram of the relative proportion of constituents in a crude paraffin petroleum is shown in Fig. 2. This diagram represents a typical paraffin petroleum fractionally distilled down to semisolid consistency, the residue amounting to 8% being represented by the area below the line *a a*. The white area A represents the paraffins and naphthenes; area B, the more stable unsaturated cyclic compounds; area C, the unstable hydrocarbons usually having an unsaturated side chain; and area D, the solid asphaltic hydrocarbons. The entire area above *a a* is considered as representing the total mixed fractions which have been distilled off. The relative percentage of the various classes of hydrocarbons in the total distillate as well as in the semisolid residue is indicated by the shaded areas. If this were done for individual fractions it would be found that all but about 2% of the first 10% fraction consists of paraffin and naphthenes, the remainder being unsaturated but stable cyclic hydrocarbons. The absence of asphaltic hydrocarbons D would be shown by practically nothing being removed when treated with fuller's earth. Failure of ordinary concentrated sulphuric acid to act upon the distillate would prove the absence of olefines and similar unsaturated hydrocarbons C. The amount removed by the action of fuming sulphuric acid would be indicated by B, and A would be those hydrocarbons unattacked by the fuming sulphuric acid. It will be noted that about 48% of the semisolid residue consists of paraffins and naphthenes and only about 2% of asphaltic hydrocarbons.

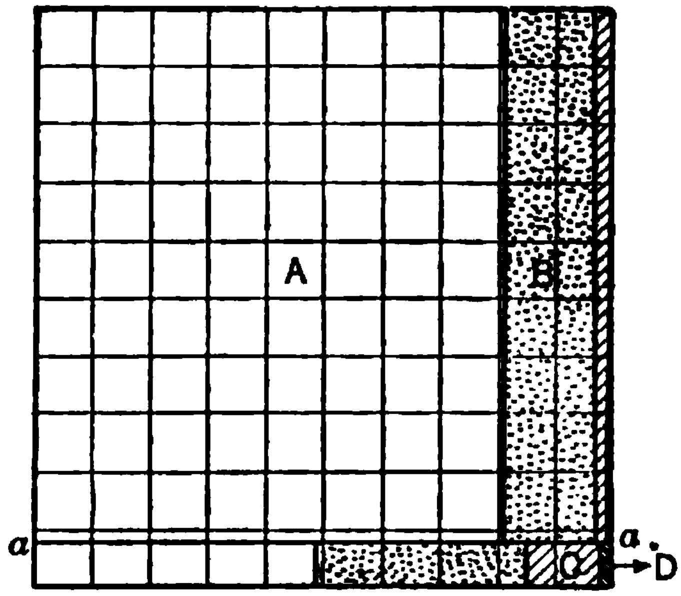

Fig. 2. Crude Paraffin Petroleum.

Asphaltic Petroleums are those in which the cyclic hydrocarbons of the C_nH_{2n}, C_nH_{2n-2}, C_nH_{2n-4} and similar series predominate in both the fluid and solid compounds present. They are usually of high gravity and upon volatilization or fractional distillation produce large percentages of semisolid and solid residues closely resembling the native asphalts in physical and chemical properties. These residues are more unstable than those obtained from paraffin petroleums but are highly cementitious, while the latter are not. The solid hydrocarbons of the C_nH_{2n+2} series are either wholly lacking in these residues or are present in very small amounts. The asphaltic petroleums yield but little light volatile distillates and the heavier distillates are often inferior for commerical purposes unless most carefully produced by vacuum or steam distillation. They are the least valuable commercially of any type of petroleum and during 1914 sold for as low as $0.38 per bbl at the well. They are, however, eminently suited to the manufacture of bituminous road and paving materials and are extensively used for this purpose. Most petroleums from the California, Mexican and Trinidad Fields may be classed as asphaltic, altho Mexican petroleums are sometimes classed as semiasphaltic. Most of the truly asphaltic petroleums occur in the United States or immediate vicinity and the use of such oils in the manufacture of bituminous road and paving materials has naturally developed in the United States to a greater extent than in any other country. For

many years their use in highway engineering was confined to the Pacific Coast where those manufactured from California petroleums were readily available. Later discovery of other petroleums which were suitable for this purpose rapidly developed the industry to one of the most important in connection with the utilization of petroleum. The relative proportion of constituents in a heavy crude asphaltic petroleum is shown in Fig. 3. The lettered areas in this diagram represent the same series of hydrocarbon constituents as described for paraffin petroleums under Fig. 2. It will be noted that the asphaltic petroleum shows a very much higher percentage of semisolid residue obtainable by fractional distillation than does the paraffin type. Moreover, the area D in this residuum has increased to about 33% against 2% for the paraffin petroleum. The paraffin and naphthene hydrocarbons A have completely disappeared in the residue, and areas B and C show a notable increase. This residue is highly cementitious and is in fact an asphalt very similar in physical and chemical properties to the bitumen of the native asphalts. In the distillates paraffin and naphthene hydrocarbons are present to a less extent than in the distillates from the paraffin petroleum. In this connection, however, it should be noted that while area A in Fig. 2 is composed mainly of paraffin hydrocarbons, area A in Fig. 3 is composed mainly of naphthene hydrocarbons. Area C has increased considerably, indicating a lower degree of chemical stability, but it is not proportionately as great as that shown in Fig. 5, which illustrates the effect of a cracking distillation upon both distillates and residue of a semiasphaltic petroleum.

Fig. 3. Crude Asphaltic Petroleum

Semiasphaltic Petroleums are those which hold an intermediate position between the paraffin and asphaltic petroleums. The distillates obtained by fractional distillation more nearly resemble those from paraffin petroleums but the cyclic hydrocarbons predominate and the naphthenes or C_nH_{2n} series largely replace the C_nH_{2n+2} series. Between given boiling points therefore the distillates from semiasphaltic petroleums have a higher specific gravity than do those from paraffin petroleums. A greater percentage of semisolid residue may be obtained from them but not usually as much as from asphaltic petroleums. These residues are very much like those obtained from asphaltic petroleums but a small quantity of the solid C_nH_{2n+2} or paraffin hydrocarbons are present. They are chemically less stable than those from paraffin petroleums but somewhat more stable than the purely asphaltic residues. Many semiasphaltic petroleums are well suited to the manufacture of bituminous road and paving materials, but, as they yield valuable distillates, they are not always primarily refined for the residues which they will yield. By means of cracking processes the yield of distillates may be increased, and this is sometimes accomplished at the expense of the quality of residue produced owing to the formation of olefines or other series of hydrocarbons containing an unsaturated open chain or side chain. When refined primarily for residues the oxidation or blowing process is often resorted to after a certain amount of preliminary distilla-

tion, as by this means the percentage of residue may be greatly increased. If the initial distillation is not carried far enough, however, semisolid residues are produced which are decidedly lacking in cementitiousness and are therefore unsatisfactory as road or paving materials. Petroleums from the Gulf, Illinois and many from the Mid-Continent and Colorado-Wyoming Fields are classed as semiasphaltic. Mexican petroleums are sometimes placed in this class because of the fact that solid paraffin hydrocarbons are found in their residues. They are peculiar, however, in the fact that they yield as high a percentage of semisolid residues and in many cases higher than do the asphaltic petroleums. The relative proportion of constituents in a typical semiasphaltic petroleum is shown in Fig. 4, while changes produced by cracking such petroleum during distillation are shown in Fig. 5.

a

Fig. 4. Crude Semiasphaltic Petroleum

Fig. 5. Semiasphaltic Petroleum, Cracked

As compared with Fig. 3, it will be noted that the area below *a a* in Fig. 4 shows approximately the same proportion of heavy asphaltic hydrocarbons D altho the area itself is considerably smaller. The proportion of other highly unsaturated hydrocarbons C is less, indicating greater chemical stability. In Fig. 5 the total area below *a a* has materially decreased owing to the increase in distillates caused by the cracking process. As compared with Fig. 4, the relative proportion of area C has been increased in both distillates and residue while the proportions of all of the other areas in the residue have decreased owing to the fact that these hydrocarbons have been broken up into distillates and the unsaturated hydrocarbons included in area C. This is particularly noticeable in regard to area B. It should be noted, however, that many of the hydrocarbons still remaining in area D have been altered chemically and are much more unstable than those in area D of Fig. 4. In this article no attempt has been made to cover the refining of petroleums, as both the methods of refining and the refined products are given under Arts. 19 to 22 inc.

NATIVE ASPHALTS

16. Origin of Native Asphalts

Occurrence of Native Asphalts. Native asphalts are semisolid or solid native bitumens which for all practical purposes may be considered as the natural residuums of semiasphaltic or asphaltic petroleums. They are

widely distributed over the earth, and history records a knowledge of their occurrence and use prior to petroleum. They are known to have been used in 2000 B.C. as a cementing material in construction of brick work in the city of Babylon. They were used for a similar purpose by the Incas of South America long before the discovery of the Americas by the white race. Evidence has also been presented of their use in highway construction by these people. They are mainly found at or near the surface of the earth, altho in certain instances they are obtained in an almost pure state from veins or seams in rock formations where they occur in much the same manner as coal. Those at or near the surface of the earth usually contain appreciable quantities of non-bituminous impurities such as water, vegetable matter and mineral matter. It is almost impossible to remove all of these impurities by refining processes so that, unless originally occurring in a pure state, the refined native asphalts do not contain as high a percentage of bitumen as do refined petroleums. Where the asphalt occurs impregnating a porous reservoir rock the entire deposit is called rock asphalt. In such cases the percentage of mineral matter is greatly in excess of the pure asphalt (see Arts. 23 and 24). When they occur at the surface of the earth as a seepage into a natural basin they are commonly known as lake asphalts. The lake asphalts are more widely known and are obtained in greater quantities than any other form of native asphalt. Their use in highway engineering in the United States preceded by many years the use of manufactured residues from semiasphaltic and asphaltic petroleums. Being themselves natural petroleum residues, their origin is identical with that of petroleum (see Art. 13).

Formation of Native Asphalts. Native asphalts are largely composed of a mixture of those hydrocarbons which originally occurred in the heavier and less volatile portions of the particular petroleums which were immediately responsible for their formation. The relative proportion and character of the original petroleum hydrocarbons may, however, have been considerably modified by peculiar conditions attending the natural processes to which they were subjected during the actual production of asphalt. These conditions were not necessarily the same as those employed in the manufacture of semisolid and solid residues from petroleums, and the native asphalts therefore often differ in certain characteristics from the manufactured petroleum asphalts. Where native asphalts are direct products of secondary distillation, they most commonly occur impregnating the original porous reservoir rock or as rock asphalts. Owing to the absence of water in the rock formation or to natural fissures in the otherwise impervious overlying strata, they may have been forced under natural pressure and at temperatures sufficiently high to have made them more or less mobile into large rock crevices where they solidified into hard mineral vein deposits. Depending upon the characteristics of the original petroleum and the temperatures and pressures to which they were subjected, the consistency of the asphalt may vary from a soft and viscous semisolid to a hard, brittle black body. A distillation under pressure might not bring them to semisolid consistency when cold but by seepage to the earth's surface and later evaporation of the more volatile hydrocarbons they might in time become solid. If subjected to high natural temperatures during formation, they might become hard and brittle. If the temperature was excessive, the hydrocarbons might be so altered that the material would be converted into one that would not melt upon the application of heat, in which case it would not be true asphalt. Such solid form of bitu-

men is most commonly known under the name of GRAHAMITE. If at high temperatures the material underwent further alteration and became insoluble in carbon disulphide, it would be known as an asphaltic coal or pyrobitumen. Should a semisolid or solid native residue be produced from a paraffin petroleum without material alteration of the paraffin hydrocarbons to cyclic or bridge compounds, these residues would more nearly resemble in chemical and physical characteristics the manufactured solid paraffin and would not be termed asphalts. Such mineral substances as OZOCERITE and HATCHETTITE belong to this class and are of no direct interest in highway engineering.

17. Production of Native Asphalts

Main Sources of Supply of Native Asphalts. Statistics relative to the world's production of native asphalts are not so complete as those for petroleum. Most statisticians include under the general heading asphalts all types of semisolid and solid native bitumens as well as rock asphalts and certain pyrobitumens. The rock asphalts in particular represent a very considerable tonnage, the importance of which from the standpoint of highway engineering is apt to be misjudged if the fact is lost sight of that most of this tonnage is represented by the rock itself and not by the asphalt which impregnates it. Trinidad and Venezuela are by far the largest producers of asphalt proper, altho the latter country shows a lower

e Not available.

tonnage than do the United States, Germany, France and Italy, whose production consists very largely of rock asphalt. The production of these materials by the largest producing countries of the world from 1904 to 1913, according to Day (16b), is given in Table III. In this connection it is of interest to note that altho asphalts have their direct origin in petroleum, the largest petroleum producing countries are not the largest producers of native asphalts. This is due to the fact that in general those formations best adapted to the collection of petroleum in paying quantities do not encourage the resultant change to asphalt or other semisolid or solid forms of bitumen.

Production and Importation of Asphalts in the United States. Semisolid and solid native bituminous materials occur in various parts of the United States. The principal producing States are Utah, California, Oklahoma, Kentucky, Texas and West Virginia. Utah produces most of the pure solid bitumens known as gilsonite, impsonite and grahamite, also the pyrobitumen wurtzilite. Some gilsonite occurs in Colorado, and grahamite is also obtained from Oklahoma and West Virginia. In 1913 California produced only bituminous sandstone. The same is true for Kentucky. Oklahoma and Texas produce both bituminous sandstone and bituminous limestone. The production by States, according to Day, (16b), from 1909 to 1913, is given in Table IV. In addition it should be noted that in 1914 a considerable deposit of solid native bitumen was discovered in the Philippines on the Island of Leyte.

a Includes wurtzilite.
b Included in bituminous rock.
c Includes maltha.
d Bituminous limestone.

The production and importation from 1909 to 1913 by the United States of native semisolid and solid bituminous materials of particular interest in highway engineering are given in Table V. For the sake of comparison the production of oil asphalts in the United States during that period is also given. From Table V it will be noted that in general the total annual production of native semisolid and solid bituminous materials has remained quite constant, the largest tonnage of actual bitumen being represented by the products known as GILSONITE and GRAHAMITE. The importation of rock asphalt has remained so low as to be of very minor importance. This is not due to lack of desirable qualities in the foreign bituminous rock but to the impracticability of its competition with native rock asphalts and the purer form of bitumen upon which transportation charges are much lower. A very large tonnage of asphalt has annually been imported from Trinidad and Bermudez, most of which has found its use in highway engineering. In 1909 this importation exceeded the production of asphalt from petroleum. The manufacture of asphalt from petroleum, however, has increased so rapidly that in 1913 it more than doubled the total importation for that year. In this connection it is of interest to note that in 1913 the importation of petroleum suitable for manufacturing asphalt was sufficient to have produced over three times the amount of oil asphalt manufactured during that year had it all been refined for that purpose. This importation was almost entirely from Mexico.

The Mining of Asphalts. Asphalts are mined in a number of ways, according to the method of occurrence and degree of hardness of the crude material. Rock asphalts are quarried in much the same manner as any rock deposit. The purer forms of solid bitumen occurring in veins of fissures below the surface of the earth are obtained as is coal by sinking a shaft to the vein formation and then removing the asphalt in lumps by means of picks. The lumps upon being elevated to the surface are sometimes sorted into a number of grades, depending upon the presence or absence of included mineral matter. GILSONITE and GRAHAMITE are thus mined and may often be obtained in a practically pure state, being free from water and mineral matter. The crude lake asphalts, such as TRINIDAD and BERMUDEZ, which are less hard, still possess sufficient solidity to make possible their removal by means of hand-pick or mattox. They are flaked up by this means and the fragments are loaded by hand upon carts or small cars which transport them to the refinery or vessels which are to carry them to the refinery. The excavations thus made gradually fill up owing to an almost imperceptible flow of the mass which seeks a constant level. Where conditions are suitable, a crane with a bucket of the clam-shell type may be used for the purpose of excavation and loading, the weight of the bucket being sufficient to cause it to sink into the mass of asphalt. Bermudez asphalt has been mined in this manner.

Transportation and Storage of Crude Asphalts. The harder varieties of crude solid bituminous materials, such as GILSONITE and GRAHAMITE, are transported from the mines by rail and usually in open cars. The lumps retain their shape under normal conditions and may, therefore, be transported and handled like so much coal. They are often of sufficient purity to require no refining other than that which will modify their consistency to that suitable to the use for which they are to serve. Lake asphalts on the other hand require refining in order to remove impurities. The lake asphalts used in the United States are transported in the crude condition to

that country, where they are refined. They are carried in vessels so constructed that practically the entire hold may be filled with the lumps of crude material, which gradually coalesce to a solid mass during transportation. This makes it necessary to again mine the material from the vessel upon its arrival at the refinery. Here it is again picked out or removed by a clam-shell bucket, and if it cannot be immediately refined and barreled, it is unloaded into an artificial pit or lake for storage, where it again coalesces. A third mining operation is then required before it eventually reaches the refining tank. Owing to its extreme viscosity and tendency to froth at elevated temperatures, it cannot be transported by pipes when heated to a molten state. At ordinary air temperatures it exhibits a strong tendency to adhere to the sides of transporting containers and for this reason the insides of such containers are usually clayed in order to facilitate removal. The cost of handling crude lake asphalt is considerably higher than for any other type of crude bituminous material, and this materially influences the market value of the refined product as compared with asphalts manufactured from petroleum.

18. Types of Native Asphalts

Classification of Asphalts. While the semisolid and solid native bituminous materials may be classified in much the same manner as petroleums under the headings paraffin and asphaltic, the asphalts themselves are usually classified by certain characteristics peculiar to a given source of supply. This is not invariably true, however, as such products as gilsonite and grahamite are obtained from a number of different localities. The individual crude asphalts of particular interest in highway engineering are treated in the following paragraphs under names by which they are commonly known to the trade. Rock asphalts or bituminous rock are not here included as they are treated under a separate subdivision. Refined asphalts are dealt with in another subdivision (see Arts. 19 to 22 inc).

Trinidad Asphalt is the best known and most extensively used of any of the native asphalts. It occurs in enormous quantities on the Island of Trinidad, which lies off the north coast of South America, being separated from the mainland of Venezuela by a narrow channel on the south and the Gulf of Paria on the west. It occurs in two forms, known as lake pitch and land pitch, which differ somewhat in properties but originate from the same source. The lake pitch or main deposit occupies what is thought to be the crater of an extinct mud volcano, while the land pitch occurs in layers which were produced by overflows from the lake. The pitch lake has an area of about 127 acres and is of unknown depth. Borings have been made to a depth of 135 ft at the center, with no indication of having reached the bottom of the deposit. The estimated minimum available tonnage of asphalt in this lake is over 9 000 000 tons.

Crude Lake Asphalt is a uniform, cheesy mixture of gas, water, fine sand, clay and bitumen, carrying about 39% of the latter constituent. It is sufficiently solid to bear the weight of men and vehicles but flows slowly and excavations made in the lake gradually fill up. After refining the bitumen carries a high percentage of sulphur containing hydrocarbons, some nitrogen but little or no oxygen. In common with other native asphalts, no solid paraffins are present but saturated cyclic hydrocarbons of the C_nH_{2n-2} series have been found. These saturated hydrocarbons amount to about 25% of the total bitumen. Polycyclic polymethylenes

similar to those contained in asphaltic petroleums are present in that portion of the bitumen which is soluble in paraffin naphtha, and extremely complex unsaturated hydrocarbons make up the bulk of the naphtha insoluble material. The crude lake asphalt is refined in order to remove the water and gas. Most of the mineral matter, however, is in such a finely divided state that it persistently remains in suspension and but little of it separates by sedimentation under the agitation to which it is necessary to subject the molten asphalt during refining in order to prevent injury by local overheating. The relative proportion of constituents in both the crude and refined lake asphalt is quite constant. They are shown in the following diagrams. It will be noticed that the refined asphalt contains about 7% of what is classed as organic matter not soluble in carbon disulphide. While it is commonly reported thus, Richardson has shown that in reality it consists mainly of water of hydration of the clay which is present, inorganic material which is volatile at the high temperature necessary to produce ash, together with about 0.3% of bitumen which is persistently retained by the fine mineral matter and cannot be removed with the solvent carbon disulphide which is used to determine the percentage of bitumen.

Fig. 6. Crude Trinidad Lake Asphalt Fig. 7. Refined Trinidad Lake Asphalt

The refined asphalt may, therefore, be considered as roughly containing 57% bitumen and 43% mineral matter. Upon ignition it yields a characteristic flesh pink ash. The high percentage of mineral matter largely limits its use to certain of the more expensive types of pavement because of the fact that in the cheaper types it cannot successfully compete in price with the purer asphalts which contain practically 100% bitumen. It has been claimed that the mineral matter in Trinidad asphalt is so uniformly distributed thruout the bitumen and exists in such a finely divided state that it makes a better filler for sheet-asphalt aggregates than will other types of pure mineral matter which have to be added for that purpose (see Sect. 17).

Crude Land Asphalt occurs in a variety of forms, depending upon its age since overflowing from the lake and also upon the natural conditions to which it has been subjected since such overflow. Different varieties are known as cheese pitch, iron pitch, cokey pitch, etc. As some of it has been coked by forest fires, and therefore injured for industrial purposes, it has to be selected with some care. It is invariably harder both in the

crude and refined state than the lake asphalt, and in general requires about half again as much flux to bring it to a given consistency or penetration. Its specific gravity is somewhat higher than the lake asphalt as it contains about 2% more mineral matter and a correspondingly lower percentage of bitumen. Nearly all of the land asphalt exported from Trinidad goes to the United States but it constitutes only a small proportion of the total. The total exportation of both types from 1909 to 1913, as given by Day (16b), is shown in Table VI. From this table it will be seen that the United States consumes considerably more than half of the total exportation.

Trinidad asphalt was first used in pavement construction in the United

States at Newark, N. J., in 1870. Its use on local roads in Trinidad antedates 1836.

Bermudez Asphalt, second only to Trinidad asphalt in the extent of its production and use, occurs as a shallow lake deposit in the State of Sucre in Venezuela, about 30 miles from the coast and almost due west of the Island of Trinidad. The pitch lake covers about 1000 acres of swampy country and is not readily accessible. It has been formed by the overflow of soft pitch or heavy maltha from a number of springs. Upon exposure the maltha liberates gas and gradually hardens. The lake varies in depth from about 2 to 9 ft. It is covered in many places by a rank vegetable growth which by catching fire from time to time has hastened the hardening of the asphalt. When mined it is quite solid for a depth of about 2 ft, but is softer than Trinidad asphalt. The fresh maltha as it exudes from the springs is practically pure bitumen, but the asphalt as mined carries appreciable quantities of extraneous matter. It is not of uniform composition in the crude state as it contains varying quantities of water, vegetable matter and mineral matter. In general the water varies from 10 to 50%, and over; vegetable matter from 1 to 6%; mineral matter from 1 to 3%; and bitumen from 45 to 88%. The refined Bermudez asphalt is much softer than refined Trinidad asphalt but carries a higher percentage of bitumen, usually 94 to 95%. The bitumen varies, however, from 92 to 97%. The vegetable matter or organic material insoluble in carbon disulphide usually lies between 1.5 and 5%, and the mineral matter or ash runs from 1.5 to 2.5%. When heated, refined Bermudez asphalt has a characteristic odor quite different from the Trinidad product. Upon ignition it yields a brownish pink ash. The vegetable matter consists of very small fragments of twigs, veins of leaves, etc, which are not

readily removed by refining. Nearly all of the Bermudez asphalt exported from Venezuela finds its way to the United States, where it is refined, fluxed and used quite extensively in highway engineering in the construction of sheet asphalt and other types of bituminous pavements. The pure bitumen of Bermudez asphalt is similar in character to that of Trinidad asphalt and carries about the same percentage of sulphur hydrocarbons. It has, however, a greater percentage of volatile hydrocarbons.

Maracaibo Asphalt is another Venezuelan product found in the State of Zulia, almost due west of the Bermudez lake. It is produced as an exudation from a maltha spring and resembles the Bermudez asphalt in many respects, altho it has a characteristic odor which readily distinguishes it from the Bermudez product. It has been used to a limited extent in the construction of sheet-asphalt pavements in the United States but is not an important source of supply from the standpoint of highway engineering in general.

Cuban Asphalts. A number of deposits of asphalt are located on the Island of Cuba and some have been worked to a limited extent. Those products which have been utilized in highway engineering to any extent are, in the crude state, hard, brittle asphalts. They carry about 75% bitumen, over 20% mineral matter, and 3 or 4% organic matter insoluble in carbon disulphide. In general appearance these Cuban asphalts resemble refined Trinidad asphalt but require a greater amount of flux to produce an asphalt cement of given consistency. Upon ignition they yield a brownish ash which is different from the Trinidad ash.

Gilsonite is a hard, brittle, lustrous material which occurs in various localities. The most important commercial deposits are, however, found in the State of Utah. It is found in rock crevices or veins from which it is picked out or mined like coal. It is ordinarily quite free from impurities and usually consists of over 99.5% bitumen. It therefore yields but little ash upon ignition. Its specific gravity generally lies between 1.04 and 1.05, altho some grades which contain more than the average amount of mineral matter may show a slightly higher gravity. Its fracture is lustrous and conchoidal. It consists of about 95% of unsaturated hydrocarbons, most of them probably being polycyclic and bridge compounds of complex structure. It melts at from 149° to 163° C (300° to 325° F) and at 205° to 218° C (400° to 425° F) may be fluxed with petroleum residuums to form asphalt cements. It has been quite extensively used in combination with blown petroleum residuums to produce rubbery, non-ductile asphalt cements sometimes known as mineral rubber. It is one of the most expensive of the crude native bituminous materials and its commercial competition with others used in highway engineering is usually limited to fluxed compounds of which it constitutes a comparatively small percentage. It is sold in two grades, firsts and seconds; the former consisting of large lumps free from powder, and the latter of smaller and more powdery fragments. As it is almost pure bitumen it does not have to be refined prior to its use in the manufacture of materials of direct interest to the trade. It is employed to a considerable extent in the manufacture of japans, paints, varnishes, electric insulations and acid-proofing materials.

Grahamite is more widely distributed in nature than gilsonite, which it resembles in hardness and brittleness. It usually occurs as vein or crevice deposits and it is mined in much the same manner as gilsonite. Oklahoma is the principal producing state. Like gilsonite, native grahamite is almost pure bitumen and does not have to be refined prior to its use in the manu-

facture of finished products. It may, however, contain as high as 5 or 6% of mineral matter. Its specific gravity is somewhat higher than gilsonite and usually lies between 1.10 and 1.20. Its fracture is irregular or hackly. It has been used to some extent in the manufacture of asphalt cements for use in highway engineering. Owing to its hardness a large amount of flux is usually required to soften it to a desirable consistency. Upon being heated it does not really melt but swells up and intumesces. In this respect it resembles the pyrobitumens. It has probably been produced in nature at comparatively high temperatures. It consists almost entirely of complex, unsaturated hydrocarbons which are practically insoluble in light paraffin naphthas. Its uses are similar to those described for gilsonite.

OTHER ASPHALTS of less importance from the standpoint of highway engineering than those above described occur in various parts of the world. Among those which have been used to a limited extent may be mentioned deposits occurring in California and Mexico, known respectively as California and Mexican asphalts. Most of the California asphalts are vein deposits of varying degrees of purity, the working of which has been largely abandoned because of their inability to commercially compete with the asphalts manufactured from California petroleums. The Mexican asphalts are principally hardened maltha effusions which occur in the vicinity of Tampico, Tuxpan and Chapapote. These deposits have not been worked to any great extent and only very limited quantities have found their way into the United States for use in the paving industry. Two other asphalts which may be mentioned are GLANCE PITCH and MANJAK. The former is widely distributed over the world but occurs principally in East Syria and Egypt. The latter is found on the island of Barbados. Both of these products are almost pure bitumens which are hard and brittle. They resemble gilsonite and grahamite in many respects. They are not used in highway engineering and their chemical and physical properties are therefore not given in the following subsection on refined petroleum and asphalt products.

REFINED PETROLEUM AND ASPHALT PRODUCTS

19. Distillation of Petroleums

Petroleum Stills. Stills for refining petroleums vary greatly in size and somewhat in construction. The refining stills most commonly used in the United States are cylindrical in form and are set horizontally in a brick framework. Another type which has in the past been used to some extent is known as the cheese-box still. It has very much the shape of a large round cheese and is set directly over the furnace, all but the bottom being exposed to the outside air. The bottom is double-curved to admit of expansion and offers a large heating surface. The modern type of petroleum still used in the manufacture of road and paving materials consists of a cylindrical steel shell set horizontally in brickwork so that the lower half is entirely concealed except at the ends. The upper half is exposed to the air except for a thin sheet metal covering. Three or four stills are usually set side by side to form a battery and are separated merely by brick partitions. They are placed in the open without covering of any sort. The large stills have a charging capacity of 1000 or 1200 bbl. They are approximately 40 ft in length and 15 ft in diameter, and are fitted with a metal dome at the top which connects with the vapor line leading to the condensers. The condenser coils consist of a number of parallel lines of pipes connecting headers which are set at successively lower elevations in a large cooling tank filled with running water. By this means more efficient cooling surface is obtained than by a single coil. The condenser discharges thru a running line which is provided with a trap for separating any uncondensed gases which may accompany the distillate. The running line con-

nects with a look-box provided with a glass door so that the stream of distillate may be watched and sampled from time to time. The outlet from the look-box leads to a manifold which connects with a number of storage tanks. The distillate may be run into any one of these storage tanks by closing all of the valves leading from the manifold but the one which will admit the distillate into the line leading to that particular tank. The look-box and manifold are located under cover in what is known as the tail-house. Fig. 8 shows a diagram of a plant such as has been described. The still is fitted with lugs which rest on roller bearings set in the brick framework in order that the expansion at high temperatures may be cared for without injury to the setting. It has three manholes, one at the top and one at each end near the bottom in order to facilitate cleaning and

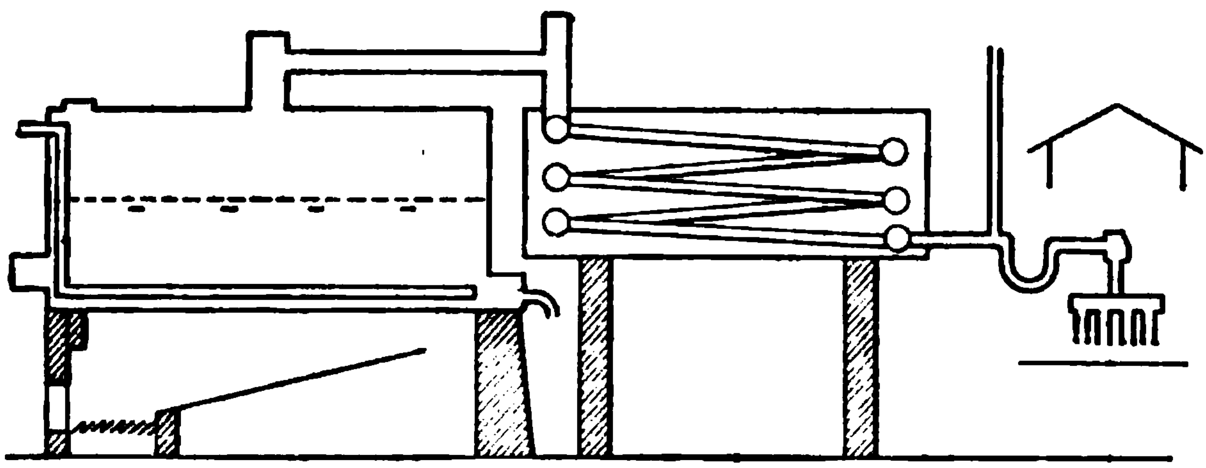

Fig. 8. Petroleum Distillation Plant

repairs. The petroleum is charged into the still thru a filling pipe from the top. One or more steam pipes are placed lengthwise in the still near the bottom. The steam pipe is fitted with spider jets deflected downward so that the oil in contact with the hottest portion of the still may be thoroly agitated during distillation, if desired, by the injection of dry steam. Metal sockets are so placed that thermometers or pyrometers may be inserted in the oil in the still and the vapor in the dome. A discharge pipe leads from near the bottom of one end of the still and connects with storage tanks or barrelling kettles by a number of branch pipes which are steam-jacketed. These tanks or kettles are usually equipped with steam coils so that their contents may always be kept sufficiently fluid to handle properly. When they are to be filled with very highly heated material from the still, they are sometimes first charged with live steam in order to prevent the hot residual from catching fire by spontaneous combustion and causing an explosion. They may also be equipped with trap doors to relieve the pressure should an explosion occur. The storage tanks or barrelling kettles are usually large enough to hold the residual contents of at least four or five stills. At any time during distillation samples of the residual petroleum may be drawn off thru a small pipe located near the bottom of the still and often tapped into the discharge pipe close to the still and between it and the main discharge valve. At the end of the distillation the discharge valve is opened and the residual material either pumped or blown by live steam into the proper storage tank or barrelling kettle. Sometimes a number of stills in a battery are set at different levels so that the residue from the first may be run by gravity into the second and so on thruout the battery. Such an arrangement is used in what is known as the continuous method of distillation. In this system, which is used to a considerable

extent in Russia, a constant flow of oil is run thru the battery of stills and the resdue is continuously discharged from the last. The single still or batch method, as most commonly employed in the United States when primarily used in the manufacture of road and paving materials, is in general conducted as follows:

Petroleum Refining. After most of the impurities have been separated by sedimentation in the storage tank, the crude petroleum may either be charged directly into the refining still or it may first be run thru a topping plant in which all of the remaining water and some of the very light oils are removed (see Art. 9). The latter is to be preferred because of the extreme care with which preliminary distillation must be conducted, even when a small quantity of water is present in the more viscous petroleums, in order to prevent foaming. Such foaming, if not carefully controlled, may result in passing most of the charge thru the vapor line and condensers. After charging, the contents of the still are slowly heated until the distillate emerges from the condenser. The gravity of the running distillate is taken from time to time by a man stationed in the tail-house. Depending upon just what distillate products are to be manufactured, cuts are made at the proper gravity by deflecting the flow to another storage tank. Owing to the tendency of asphaltic petroleums to crack during distillation (see Art. 10) as soon as the vapor temperature is sufficiently high to prevent condensation within the still, live steam is forced thru the steam pipe. The distillate then becomes a mixture of oil and water which, however, readily separates by gravity. Samples of the residual material remaining in the still are also taken from time to time and tested for consistency and other properties which are to be secured. When the proper consistency has been obtained, the distillation is stopped and the residual discharged into the cooler, storage tank or barrelling tank. After acquiring experience with any particular type of oil, the manufacturer is able to gage with considerable accuracy what characteristics are possessed by the residual, from the quantity and gravity of the distillate that has been removed. Very frequent sampling of the residual is not therefore always necessary. As some of the tests for consistency require an hour or more to make, it is evident that if distillation is continued while the test is being made, the residual will have changed appreciably during that period. Exact control is therefore largely a matter of experience and knowledge of what the results of a given test indicate as regards the residual in the still at the

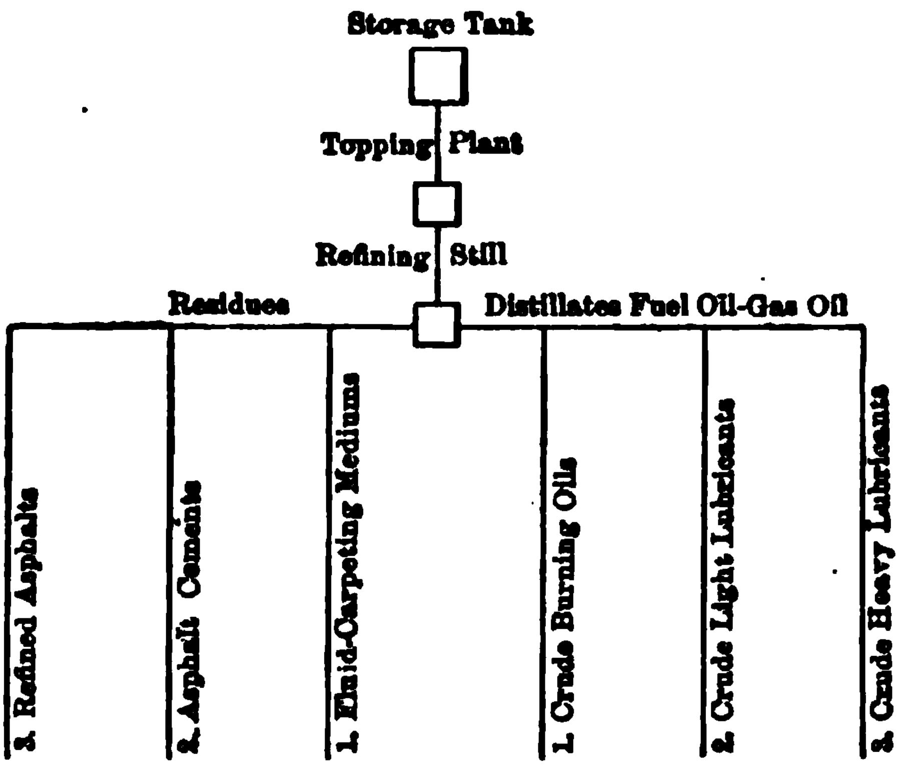

Fig. 9. Distillation of Asphaltic Petroleum

expiration of the test. Sometimes distillation is inadvertently carried beyond the proper point for the production of a given product. In such case the residual may sometimes be utilized by running it into the cooler and there mixing with it the residue from another distillation which has not been carried quite far enough. Various modifications in a given method of distillation are necessary to produce the various products which may be required. Fig. 9, however, serves to illustrate in general, the practice followed in the manufacture of straight residuals for use in highway engineering, and their accompanying distillates, from a crude asphaltic petroleum. As the quantity of distillate removed from a given charge of petroleum increases, the residual remaining in the still becomes more and more viscous until finally it will solidify upon cooling. In most cases the residual is a finished product after it has been discharged from the still, and requires no further treatment. Distillates, however, are usually further refined by redistillation in a smaller still and subsequent agitation with concentrated sulphuric acid, followed by washing with a solution of caustic soda and finally with water. The sulphuric acid combines with and polymerizes the unsaturated compounds which are present and forms a sludge acid which separates by gravity from the purified distillate. The sludge acid may then be treated for the recovery of the sulphuric acid, leaving behind the hydrocarbons which have been removed from the distillate. When the distillates are of inferior quality for the manufacture of refined products or when market conditions do not warrant their further refining, they are sometimes run into a common tank after the lightest fraction has been separated, and are sold as fuel oil distillate. Refined distillates are sold under the names of gasoline, kerosene, burning oils, turpentine substitutes, spindle oils, cylinder oils, dust layers, etc. The residues of various consistency are sold as dust layers, carpeting mediums, fluxes, asphalt cements and refined asphalts. For further details and principles governing distillation in general, see Art. 10.

Distillate Dust Layers are usually heavy non-volatile distillates which may have been treated with sufficient sulphuric acid to remove all objectionable odor, due to the presence of hydrocarbon derivatives containing sulphur. They are usually transparent or semitransparent and vary in color from pale yellow to dark brownish red. They resemble and are, in effect, inferior lubricating oils which flow readily at ordinary temperature and do not possess or develop after application any true cementitiousness. Their function is to lay dust in much the same manner as water but, being non-volatile, their effect is more permanent than water. They should be used sparingly or otherwise there is danger of disintegration of the road surface thru the medium of their lubricating action. As a rule they are sufficiently fluid to apply to a road surface by means of an ordinary street sprinkler, but a pressure distributor is to be preferred for this purpose in order to secure a very light, uniform distribution. Their consistency is determined by means of a viscosimeter, the test being ordinarily made at 25° C (77° F). The physical and chemical characteristics of a typical distillate dust layer are as follows:

Distillate Dust Layer

Specific gravity 25°/25° C (77°/77° F)	0.892
Specific viscosity (Engler) 50 cu cm, 25° C (77° F)	3.4
Flash point (closed cup)	105° C (221° F)
Burning point (closed cup)	158° C (316° F)
Loss at 163° C (325° F), 5 hr, 50 g	12.6%
Character of residue	Fluid

Soluble in carbon disulphide (total bitumen)	100.00%
Organic matter insoluble	0.00%
Inorganic matter insoluble (ash)	0.00%
	100.00%
Bitumen insoluble in 86° B naphtha	0.00%
Bitumen insoluble in carbon tetrachloride	0.00%
Fixed carbon	0.40%

All distillate dust layers are completely soluble in carbon disulphide, 86° B naphtha and carbon tetrachloride. They seldom, if ever, exceed 0.920 specific gravity or 12.0 specific viscosity. Their flash point, burning point and loss by volatilization vary considerably, the first two properties increasing and the last decreasing with the specific gravity. The residue from the volatilization test is invariably fluid and greasy. They yield a low percentage of fixed carbon, seldom over 1.0%, and upon ignition should be free from ash. Their physical and chemical properties change but little after application, and their value as dust layers lasts only so long as they are not supersaturated with dust particles. If used in excessive quantities they produce an oily, muddy emulsion in wet weather, as they do not serve as waterproofing agents.

Crude and Residual Dust Layers. In some cases crude petroleums are sold and used directly as dust layers. As a rule, however, the manufacturer or producer prefers to remove some of the lighter and more valuable distillates. This may be done either by running the oil thru a topping plant or subjecting it to fractional distillation. The former practice is common with the viscous asphaltic crude oils while the more fluid semi-asphaltic oils are subjected to distillation. For cold application the character of a topped oil is not materially different from the original crude altho its specific gravity, specific viscosity, flash point and burning point are slightly increased and its loss by volatilization decreased. Some crude oils are too viscous to be used directly as dust layers, in which case either the original crude or the topped crude may be thinned down to suitable viscosity by adding the proper quantity of some cheap petroleum distillate, such as a distillate dust layer or burning oil fraction. These materials vary greatly in character according to the crude oil from which they are produced and their method of manufacture which is difficult to determine exactly by ordinary routine tests. Their function is similar to that of the distillate dust layers altho they prove effective for a longer period, owing to the fact that they form a thin superficial coat upon the surface treated. They should be sufficiently fluid to apply cold by means of a pressure distributor at a rate of not over ⅙ gal per sq yd. Altho they often contain appreciable amounts of the heavier asphaltic hydrocarbons and upon prolonged exposure in thin films may develop some adhesiveness, they do not harden after application with sufficient rapidity to be used in the construction of bituminous carpets. If used in excessive quantities they either act as lubricants or product a greasy black mud in wet weather. They are brownish black in color and most of them resemble crude petroleum in general appearance. The following analyses are typical of crude and residual petroleums which have been marketed for cold surface application.

Crude Heavy Asphaltic Petroleum

Specific gravity 25°/25° C (77°/77° F)	0.962
Specific viscosity (Engler) 50 cu cm, 25° C (77° F)	139.5
Flash point (closed cup)	45° C (113° F)
Burning point (closed cup)	67° C (153° F)
Loss at 163° C (325° F), 5 hr, 50 g	24.8%
Character of residue	Viscous fluid

Soluble in carbon disulphide (total bitumen)	99.80%
Organic matter insoluble	0.15%
Inorganic matter insoluble (ash)	0.05%
	100.00%

Bitumen insoluble in 86° B naphtha	10.62%
Bitumen insoluble in carbon tetrachloride	0.00%
Fixed carbon	5.10%

Topped Medium Asphaltic Petroleum

Specific gravity 25°/25° C (77°/77° F)	0.938
Specific viscosity (Engler) 50 cu cm, 25° C (77° F)	56.2
Flash point (closed cup)	130° C (266° F)
Burning point (closed cup)	145° C (293° F)
Loss at 163° C (325° F), 5 hr, 50 g	26.8%
Character of residue	Viscous fluid

Soluble in carbon disulphide (total bitumen)	99.91%
Organic matter insoluble	0.05%
Inorganic matter insoluble (ash)	0.04%
	100.00%

Bitumen insoluble in 86° B naphtha	12.90%
Bitumen insoluble in carbon tetrachloride	0.00%
Fixed carbon	6.40%

Most of the crude and residual petroleums sold as dust layers have a specific gravity of between 0.930 and 0.980. Their specific viscosities at 25° C (77° F) in general vary from about 25 to 140. Many of them are too viscous for successful cold application. Upon being subjected to the volatilization test at 163° C (325° F) for 5 hr they usually lose from 8 to 30% and the residues thus produced are usually fluid. They seldom yield over 7% fixed carbon but may show as high as 15 or 18% of bitumen insoluble in 86° B naphtha. Those produced from light semiasphaltic petroleums may show 2% or less of naphtha insoluble bitumen. They are almost entirely soluble in carbon disulphide and also in carbon tetrachloride.

Residual Fluxes are fluid petroleum residuums preferably carrying a minimum amount of volatile material. They are used primarily for the purpose of softening refined asphalts, especially the native asphalts which are too hard to be directly available for use in highway engineering. Those produced from paraffin petroleums usually have a specific gravity of from 0.920 to 0.940. The gravities of the semiasphaltic fluxes lie between 0.940 and 0.975, while the asphaltic fluxes run from 0.975 to 1.01 and over. In general their flash point should be well above 163° C (325° F) as this is the temperature to which they are likely to be heated when being combined with the solid asphalts. They should not lose over 5% by weight when subjected to the volatilization test for 5 hr at 163° C (325° F). The residues from this test may or may not harden appreciably but the degree of hardening should never cause the asphalt cement in which they are incorporated to show a loss of over 50% in penetration when subjected to the volatilization test at 163° C (325° F). In this respect they differ from the most desirable type of residual carpeting medium. The characteristics of certain typical residual fluxes available in 1914, as given by Forrest (20c), are shown in Table VII. In general, as fluxes increase in specific gravity, they must

Table VII.—Residual Fluxes

Specific gravity 15.5° C (60° F)	0.931	0.961	1.01
Baumé gravity	20.4°	15.7°	heavy
Flash point	205° C (401° F)	268° C (514° F)	166° C (331° F)
Loss at 163° C (325° F) 5 hr, 50 g	0.62%	0.14%	2.22%
Residue, float test at 65° C (149° F)	Too soft	20 sec	60 sec
Soluble in carbon disulphide (total bitumen)	99.80%	99.50%	99.80%
Paraffin scale	4.42%	2.96%	0.65%
Sulphur	0.63%	0.43%	3.33%

be used in greater quantity with a given refined asphalt to produce an asphalt cement of given penetration. The asphaltic fluxes usually show a higher loss by the volatilization test than do the paraffin and semiasphaltic fluxes. This is due to the fact that in their manufacture distillation cannot be carried to as high a temperature because the asphaltic residual would become too hard for use as a flux if distilled to the same temperature as the paraffin and semiasphaltic petroleums. This is also shown by the relatively low flash point of most asphaltic fluxes.

Residual Carpeting Mediums are products not unlike certain of the very heavy residual fluxes. They are too viscous to apply cold but when heated should be sufficiently fluid to be capable of uniform distribution over a road surface at the rate of not over ½ gal per sq yd if applied by means of a pressure distributor. They should either possess considerable cementitiousness or develop after application sufficient cementitiousness to properly perform their function, which is that of adhering to the road surface and holding in place the covering of fine aggregate with which they combine to form a bituminous carpet. Those which harden appreciably when subjected to the volatilization test are to be preferred. Many of the residual petroleums used as carpeting mediums are entirely unsuited for the purpose because they are too fluid to possess the requisite degree of cementitiousness, and during manufacture have been distilled at such high temperature that all chance of loss by volatilization, to a sufficient extent to cause appreciable hardening after application, has been eliminated. On the other hand, if they originally possess sufficient consistency or stability to serve adequately as bituminous cements for the mineral aggregate of the carpet, it is often difficult, if not impossible, to distribute them uniformly, and at the proper rate, over the road surface. Soft asphalt cements fluxed to proper consistency with a volatile distillate possess certain advantages over the straight residual carpeting mediums, especially for use on broken stone and gravel roadways. The characteristics of residual petroleums which have been used as carpeting mediums are shown in Table VIII. For the reasons above mentioned, No. 1 is unsuitable for use in this connection, while No. 2, altho showing reasonably satisfactory physical and chemical characteristics, is more difficult to apply properly.

Asphalt Cements from Petroleum produced by straight distillation vary in characteristics according to the type of petroleum distilled and the purpose for which the asphalt cement is prepared. Those intended for use in bituminous macadam construction are usually softer than for use in bituminous concrete or sheet asphalt pavements. In general the finer the mineral aggregate which is to be cemented, the lower should be the penetration of the asphalt cement. This is due to the fact that fine aggregates

Table VIII.—Residual Carpeting Mediums

	(1)	(2)
Specific gravity 25°/25° C (77°/77° F)	1.010	1.001
Float test at 50° C (122° F)	viscous fluid	60 sec
Flash point (closed cup)	196° C (385° F)	173° C (343° F)
Loss 163° C, (325° F) 5 hr, 50 g	2.50	3.75
Residue, float test at 50° C (122° F)	Too soft	96 sec
Soluble in carbon disulphide (total bitumen)	99.91%	99.86%
Organic matter insoluble	0.06%	0.07%
Inorganic matter insoluble (ash)	0.05%	0.07%
	100.00%	100.00%

Bitumen insoluble in carbon tetrachloride	0.00%	0.00%
Fixed carbon	11.50%	7.00%

have less inherent mechanical stability in a pavement than coarse aggregates and therefore require a more solid and harder cement to hold the mineral particles in place. The most desirable penetration for asphalt cements for a given type of pavement varies with the type of oil from which they are produced. The penetration test is the principal control test used in their manufacture and as the penetration or consistency varies, so also will the other physical and chemical properties. These variations differ somewhat, however, for asphalts produced from different types of petroleum and are often greatly modified by variations in the method of distillation. Table IX illustrates the general scope and character of these variations, as applied to asphalt cements of different penetrations produced by straight distillation of the same crude petroleum. The actual test values are not typical of all asphalt cements of the same penetration produced from different petroleums and should not be so interpreted. Considering the first three analyses it will be noticed that as the penetration at 25° C (77° F) decreases, the specific gravity, flash point, melting point, naphtha insoluble bitumen, and fixed carbon gradually increase. The ductility, loss by volatilization and penetration of residue, on the other hand, decrease. The solubility in carbon disulphide and carbon tetrachloride, however, remain about the same. The fourth analysis represents an asphalt cement which has been badly injured by cracking during the distillation process. While its penetration at 25° C (77° F) is the same as that shown by No. 3, its penetration at 4° C (39° F) is very much lower, showing extreme susceptibility to temperature changes. Its melting point has decreased somewhat and also its ductility. It shows a notable increase in loss by volatilization at 163° C (325° F) and under this test produces a very hard residue, as shown by the low penetration. Cracking is directly shown by the presence of nearly 2% of organic material insoluble in carbon disulphide and also by the high percentage of its bitumen which is insoluble in carbon tetrachloride. If examined under the microscope the organic material insoluble in carbon disulphide would be found to resemble soot and to be, in fact, amorphous carbon produced by decomposition of some of the heavy hydrocarbons of the original petroleum. The percentage of bitumen insoluble in 86° B naphtha has notably increased as has also the percentage

Table IX.—Asphalt Cements Produced by Straight Distillation

	(1)	(2)	(3)	(4)

of fixed carbon. All asphalt cements which have been injured by cracking do not exhibit such marked changes as shown above. The exact changes are largely dependent upon the extent of cracking and original character of the petroleum distilled. The preliminary stages of cracking are sometimes indicated by only one or two tests in the interpretation of which care must be taken to first identify the original petroleum. As a means of general comparison the relative characteristics of typical asphalt cements of approximately the same penetration produced by distillation of Texas, California, and Mexican petroleums are shown in Table X.

Table X.—Asphalt Cements from Various Petroleums

Petroleum	Texas	California	Mexican
Specific gravity 25°/25° C (77°/77° F)	1.020	1.035	1.047
Flash point	205° C+ (401° F+)	205° C+ (401° F+)	205° C+ (401° F+)
Penetration at 25° C (77° F)	95	85	90
Penetration at 4° C (39° F)	43	18	30

Sulphur	0.75%	1.19%	4.95%

Refined Asphalts from Petroleum are similar in character to asphalt cements produced by distillation of the same petroleum. The term refined asphalt, or R.A., usually implies that the material is too hard to be used in highway construction without first fluxing it with a residual flux to softer consistency or higher penetration. Refined asphalts may, therefore, be considered as very hard asphalt cements. If carefully prepared they differ only from the softer asphalt cements in those properties which have been shown to change by a gradual increase or decrease as the result of continued distillation. Their penetration at 25° C (77° F) is usually 40 or less. They may be softened to any desired penetration by combining with them the proper proportion of suitable flux. They are mainly used in connection with the construction of sheet asphalt pavements where it is desired to control and to modify, at the paving plant, the consistency of the asphalt cement which is used. This practice has been handed down from the days when only refined native asphalts were used to any extent in sheet asphalt construction. Since then, however, many municipalities have learned what penetration of various asphalt cements is most desirable to meet their local conditions of climate, traffic, aggregate, etc, and as the manufacturers can meet penetration requirements within very close limits, there is a general tendency to purchase ready prepared asphalt cements rather than to purchase separately and afterward combine the refined asphalt and flux. There is much to be said for the old practice where careful control at the paving plant is assured, but the ready prepared asphalt cements have found favor in the smaller types of plants, particularly in connection with bituminous concrete construction, where a coarse aggregate is used. Ready prepared asphalt cements are, moreover, almost invariably used in bituminous macadam construction.

Sludge Asphalts are sometimes produced as by-products in the purification of petroleum distillates. These distillates are agitated with concentrated sulphuric acid in lead-lined agitators. The sulphuric acid combines with and produces certain hydrocarbons of an asphalt-like nature which are removed as sludge acid. Upon subsequent dilution with water, the sludge acid breaks down, and upon standing, the hydrocarbons, which have been removed or formed from the original distillate, rise to the surface of the solution and may be separated from the dilute acid which is afterward concentrated and recovered for the further purification of distillates. The separated oil is usually viscous and shows a strong acid reaction. It is called acid sludge and is sometimes fractionally distilled until a semisolid residue, known as sludge asphalt, is obtained. Sludge asphalts are acted upon by water and are not generally considered suitable for use in the treatment or construction of highways. In the early days of petroleum refining they were considered as waste products and, as they could not be conveniently disposed of, they were sometimes run into large pits dug in the ground. A large deposit of this nature accumulated at an old refinery near Baltimore, Md., and there remained for many years. The sludge asphalt probably underwent considerable change in chemical and physical properties during this period and some time later this product, which had become saturated with water, was mined from the pit, heated in open kettles until fluid, the acid neutralized with caustic soda, and the resulting salt solution separated by gravity. The asphalt was then fluxed to desired consistency and used to some extent in the treatment and construction of highways. It was found to be highly resistant to water action. Such old deposits, however, are of minor importance owing to the fact that they

are of rare occurrence. The manufacture of asphalt from this source is also attended with considerable difficulty and such asphalt has not been used to any great extent.

20. The Blowing of Petroleums

Blowing Stills or Kettles used in the oxidation of petroleums for the purpose of producing asphalts are much alike in principle but may be divided into two types. (1) Those in which the air is pulled or sucked thru the charge of petroleum, and (2) those in which it is forced thru under pressure. In 1894 Francis X. Byerley patented in the United States a process for the manufacture of asphalt from petroleum by means of the action of air upon the heated material. Byerley's apparatus consisted of a cylindrical vertical still thru the head of which were inserted a number of vertical pipes extending almost to the bottom of the still and dipping well into the charge of petroleum or petroleum residuum. The upper ends of these pipes were open. A pipe or gooseneck connected the upper part of the still, or vapor space, with a coil condenser which discharged into a receiving tank. The receiving tank was hermetically closed with the exception of the inlet pipe and one other which led from the top to the suction port of an air pump. The Byerley apparatus was operated by means of the pump which created a partial vacuum in the still, thus causing the atmospheric pressure to force air thru the vertical pipes extending into the charge of petroleum and to thus thoroly agitate it with air. In 1899 the United States Patent Office granted a patent to Culmer and Culmer for a process of making asphaltic fluxes by means of the action of air upon heated petroleum residuums. The Culmer apparatus consisted of an open kettle set in brickwork over a furnace, the bottom being protected from direct fire by means of a brick arch. The kettle was provided with a draw-off, operated by a valve, and located at one end near the bottom. The petroleum was run into the kettle from a pipe which did not form a part of the apparatus proper. A vertical pipe connected with a pressure pump reached almost to the bottom of the kettle. This pipe connected with a longitudinal pipe which extended along the bottom of the kettle, and which was either perforated along its entire length or carried a number of perforated side branch pipes capped at the ends. By this means air

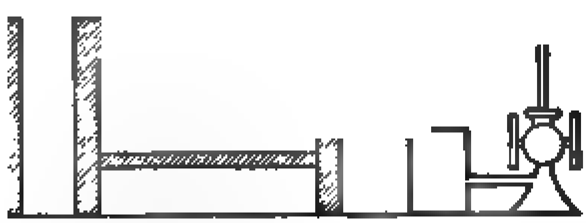

Fig. 10. Culmer Blowing Kettle

could be forced by the pump thru the piping system into the charge of petroleum residuum. The air supply was controlled by means of a valve located outside of the kettle in the main supply line. This apparatus was designed to handle non-volatile petroleum residuums and no provision was made for distillation. The Culmer type of blowing kettle is shown in Fig. 10.

In connection with this kettle a later device was used for removing any volatile products formed during the blowing process. This device consisted of a conical hood fitting closely over the top of the kettle and connecting at its apex with a large exhaust pipe thru which the volatile products were pulled by means of an exhaust pump or fan. The modern blowing apparatus holds a charge of from 2000 to 5000 gal, and makes use of the principle of injecting air, into and thru the heated petroleum, under greater than atmospheric pressure rather than to pull it thru by means of an exhaust or partial vacuum imposed upon the charge itself. The charge is often heated by means of a coil thru which is passed superheated steam instead of by direct fire. In some instances the blowing process is conducted in an horizontal cylindrical still, the dome being open and hooded. Sometimes it is conducted in an ordinary type of still fitted with piping similar to that for the injection of steam during steam distillation. In general, however, the blowing stills are not designed for the manufacture of distillates.

The Blowing Process. There are a number of variations in the blowing process as practiced in modern refineries, depending upon the character of material which is to be produced. In the preparation of bituminous materials for use in highway engineering, both semiasphaltic and asphaltic fluid petroleum residuums and soft asphalt cements are often subjected to the blowing process. The action of the air becomes very pronounced when the material is heated to about 220° C (425° F) and the air is injected so as to produce copious agitation. An exothermic reaction is then induced which often produces enough heat to make other means of heating unnecessary thruout the process. It is necessary to exercise considerable care in the manipulation of the air supply or the temperature of the charge may otherwise be raised considerably above its flash point and a serious explosion result from spontaneous combustion. The exact reactions involved are complex and varied in character. A small amount of oxygen from the air may combine with some of the hydrocarbons, but the general type of reaction seems to be one of nucleus condensation in which an atom of oxygen combines with two atoms of hydrogen or two hydrocarbon radicals which it splits off from two different molecules. It is then eliminated as water or volatile oxygen derivatives of the hydrocarbons. Meanwhile the radicals produced in the residuum join together to form a single heavier and more complex hydrocarbon. One of the simplest forms of this type of reaction may be considered as taking place between two monocyclic polymethylene molecules and one oxygen atom, with the production of a single dicyclic polymethylene and one molecule of water. Such a reaction may be graphically illustrated as follows, altho this particular reaction does not actually take place because the original hexamethylene molecules are not present in petroleum residuums but only in crude petroleums.

2. 
Owing to the formation of various radicals in the charge, exceedingly complex nucleus condensation products are probably formed which contain

a number of cycles in the molecule. In any event, even when the original material contains no hydrocarbons volatile at the temperature at which it is blown, it undergoes a marked change in many of its physical and chemical properties. If originally fluid it gradually begins to thicken and become more viscous until finally it attains semisolid consistency upon cooling. If blowing is continued, it becomes more and more solid. Its melting point increases markedly, altho its specific gravity changes but slightly. The action of the air also increases the percentage of bitumen which is insoluble in 86° B naphtha and at the same time raises its percentage of fixed carbon but to a less noticeable extent.

Blown Petroleums from Fluid Residues. If fluid petroleum residuums are blown to the consistency of asphalt cements, such cements are invariably short and non-ductile. If the original residuum was very fluid they are greasy or cheesy and lack cementitiousness. They may then have a very high melting point and at the same time show an exceedingly high penetration, or, in other words, be very soft. Blown fluid residues of the same consistency, or showing the same float test as the better types of straight distilled carpeting mediums, are wholly unsuited for use in this connection. If the original petroleum is semiasphaltic or asphaltic in character and first distilled to a very viscous residue, it may be converted to an asphalt cement possessing some cementitiousness, but not always as desirable as tho the original distillation had been carried to the production of a very soft asphalt cement and afterward blown to the desired penetration. The latter practice is fortunately in more common use.

Blown Oil-Gilsonite Asphalt Cements. One of the most satisfactory types of asphalt cement, produced primarily by blowing fluid residuums, is that which has been reinforced by combining it with gilsonite which imparts a considerable degree of adhesiveness and produces a peculiarly rubbery product. Unfortunately, it is difficult to positively identify such products by the ordinary analytical methods as products showing very

Table XI.—Gilsonite and Blown Oil-Gilsonite Asphalt Cement

Material	Gilsonite	A.C.
Specific gravity 25°/25° C (77°/77° F)	1.040	0.980

Loss 163° C (325° F), 5 hr, 50 g	0.4 %	0.13%
Penetration of residue at 25° C (77° F)	0	55
Soluble in CS_2 (total bitumen)	99.77%	99.91%
Organic matter insoluble	0.04%	0.05%
Inorganic matter insoluble (ash)	0.19%	0.04%
	100.00%	100.00%
Bitumen insoluble in 86° B naphtha	53.73%	25.00%
Bitumen insoluble in CCl_4	0.00%	0.03%
Fixed carbon	13.70%	9.80%
Paraffin scale	0.00%	1.60%
Sulphur	1.70%	0.70%

similar characteristics may be produced by blowing certain soft asphalt cements to harder consistency. They consist of a relatively small amount of gilsonite which is added to the contents of the blowing kettle or still after the fluid residuum has been blown to the desired melting point. It may then be cheesy or greasy and should properly be considered in the light of a very heavy flux. After the gilsonite has been added the blowing process is continued for some time before the finished product is drawn from the still. The analysis of a typical asphalt cement of this nature is shown in Table XI. The analysis of a specimen of gilsonite is also given.

Partially Blown Oil Asphalts. Fillers. If distillation of a semiasphaltic or asphaltic petroleum is carried to the production of a very soft asphalt cement, say of 300 penetration, cementitiousness is assured, and such product may then be blown to any desired lower penetration. The blowing process then imparts certain desirable properties which cannot be secured in any other way. The melting point of the asphalt cement is materially raised and its susceptibility to temperature changes is greatly lessened. It becomes more or less rubbery in character and is admirably suited for use as a seal coating material on certain types of bituminous concrete pavements containing a coarse aggregate. Such products, when prepared for use as a filler for brick or block pavements, are sometimes cast or molded into strips which may be placed in the pavement without preheating or pouring and thus serve as expansion joints. The strips may also consist of a mastic produced by combining with the asphalt cement fine mineral matter, such as limestone dust or silica. They are made of varying width and thickness to suit the different types of pavement. When not manufactured as ready prepared strips or expansion joints, the fillers have to be heated to a rather high temperature before pouring them into the joints of the pavement. Partially blown asphalt cements may usually be distinguished from asphalt cements produced by blowing fluid residuums, by their higher specific gravity and lower penetration for approximately the same melting point. They may be more or less ductile, according to the character of the asphalt cement before blowing and the length of time that they are blown. The characteristics of a partly blown asphalt cement are shown in the following analysis.

Partly Blown Asphalt Cement

Specific gravity 25°/25° C (77°/77° F)	0.999
Flash point	205° C + (401° F +)
Penetration at 25° C (77° F)	45
Penetration at 4° C (39° F)	28
Penetration at 46° C (115° F)	67
Melting point	82° C (180° F)
Ductility 25° C (77° F) cm	4
Loss at 163° C (325° F), 5 hr, 50 g	0.3 %

Organic matter insoluble	0.10%
Inorganic matter insoluble (ash)	0.02%
	100.00%
Bitumen insoluble in 86° B naphtha	31.20%
Bitumen insoluble in CCl_4	0.08%
Fixed carbon	10.10%
Paraffin scale	0.40%
Sulphur	0.71%

21. The Emulsification of Petroleum Products

The Emulsifying Process. Petroleum products are insoluble in water. Unlike the vegetable and animal oils and fats, they are not directly saponifiable and will not combine with the alkalies, such as caustic soda, to produce soluble soaps. In order to produce thin, dilute emulsions of petroleum products and water it is necessary to first thoroly mix them with a soap or soap solution. Sometimes the ingredients of the soap are added separately, after which the material may be mixed with water to almost any extent. Such products are manufactured and sold as emulsifying oils. Sometimes, particularly in the case of asphalt emulsions, a certain amount of water is added during the manufacturing process so as to produce a thick viscous emulsion which may be diluted with water prior to its use in highway treatment or construction. The emulsifying agents commonly employed are commercial oleic acid, known as elaine, or cottonseed oil, in combination with caustic soda, potash or ammonia. Carbolic acid, pine oil and various other materials are sometimes used in the preparation of these emulsions for the purpose of assisting the process of emulsification. The satisfactory emulsification of asphalt cements is often a difficult matter because of the rather delicate and unstable equilibrium of the suspended bituminous material which tends to separate from the water upon slight provocation. Crude petroleums and fluid petroleum residuums are, however, not so difficult to emulsify and the apparatus is not complicated. For the preparation of such emulsions in dilute form ready for application, a hot soap solution is first prepared in a tank, the bottom of which is connected with a circulating pump which produces agitation by discharging back into the tank. The desired amount of fluid petroleum residuum is then run into the tank, the contents of which are circulated thru the pump until the emulsification is completed. The emulsion may then be further diluted if required.

Emulsifying Oils. Fluid residual petroleums which have been emulsified or prepared for emulsification can be considered only as dust layers and not as carpeting mediums whether prepared from semiasphaltic or asphaltic petroleums. They possess the advantage of easy application at almost any desired rate and have been used to a considerable extent as dust layers for park highways. In general, the manufactured emulsifying oils resemble the ordinary fluid petroleum residuums in appearance. Owing to the fact that the emulsifying agents are to a large extent soluble in carbon disulphide, they are apt to escape notice in ordinary routine examination. The products produce a brown, milky, uniform emulsion with water and, upon standing, the bitumen usually remains in suspension for a considerable period of time before separation commences. Upon application of a dilute emulsion to a road surface the water gradually evaporates and leaves behind a film of the original residuum, which is usually rather greasy in character. The characteristics of a manufactured emulsifying oil are shown in the following analysis:

Emulsifying Oil

Specific gravity 25°/25° C (77°/77° F)	0.796
Flash point	173° C (343° F)
Specific viscosity (Engler) 50 cu cm, 50° C (122° F)	23.6
Loss at 163° C (325° F), 5 hr, 20 g	14.75%
Character of residue	Fluid

Soluble in CS_2	99.80%
Organic matter insoluble	0.02%
Inorganic matter insoluble	0.00%
	100.00%
Total insoluble in 86° B naphtha	1.20%
Fixed carbon	3.90%
Ash recovered as alkaline carbonate	3.36%

Asphalt Cement Emulsions. Manufactured emulsions of asphalt cement usually contain a considerable amount of water and for this reason they are often dried at 100° C (212° F), prior to making certain physical and chemical tests. They hold an intermediate position between the petroleum dust layers or dust palliatives and the carpeting mediums. They are usually applied in dilute solution, but after the water evaporates a film of asphalt cement is left over the road surface which eventually becomes quite waterproof and refuses to again emulsify. Successive and frequent applications of such emulsions tend to produce a very thin bituminous carpet which seldom requires a covering. Emulsions of asphalt cement have also been used in the construction of cold mixed bituminous concrete pavements. When so used a considerable period of time is required for the water to evaporate sufficiently to develop the necessary consistency of bituminous cement which such highways demand. As a result, the newly constructed highway must be closed to traffic for some time and this fact has greatly limited their use in this direction. The characteristics of an asphalt cement emulsion are shown in the following analysis:

Asphalt Cement Emulsion

Specific gravity 25°/25° C (77°/77° F)	0.973
Loss in air 24 hr	6.14%
Additional loss at 105° C (221° F), 5 hr	18.62%
Dried emulsifying asphalt cement	75.24%
	100.00%
Examination of dried material	
Penetration at 25° C	221
Soluble in CS_2	96.90%

22. The Fluxing of Asphalts

Fluxing Tanks or Kettles may be heated either by fire or steam, the latter method being preferable because the heat may be more easily regulated and more evenly applied. It also involves less danger of overheating and thereby injuring the asphalt cement. The fire heated tanks have a rounded bottom and are set in a furnace so that the bottom is protected from direct flame by a firebrick arch. They may be either cylindrical or rectangular in shape. They are most commonly used in small portable paving plants. The steam heated kettles are used in the larger paving plants and at refineries, and are generally constructed of sheet metal. They vary in size but are usually rectangular in shape and have flat bottoms. In such tanks heat is applied by means of gangs of narrow horizontal coils carrying steam under pressure. The coils are placed in the bottom of the tank and extend up for about half its height. A number of perforated pipes, capped at one end and extending along the bottom of the tank, are used as a means of injecting live steam or air into the mass of heated material and thus securing thoro agitation, which is essential for uniform fluxing. In the fire heated kettles steam and air are also used as a means of agitation, altho in the older types mechanical agitators of the paddle-wheel type were sometimes used. Fig. 11 shows the general construction of a steam heated tank The top is left open and admits of easy filling, while a pipe operated by a valve and located at one end near the bottom of the tank serves as a draw off.

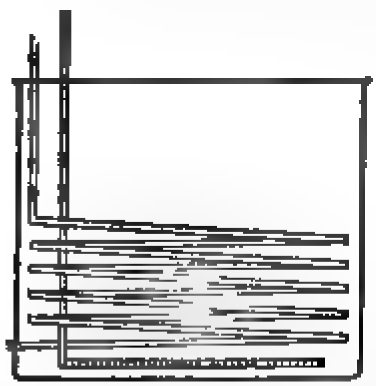

Fig. 11. Fluxing Tank

The Fluxing Process usually consists in combining a refined asphalt with a petroleum residuum or flux in such proportions as to produce an asphalt cement of any desired consistency. The refined asphalt, which is hard enough to handle in fragments, is first placed in the fluxing tank where it is melted and brought to a temperature of about 163° C (325° F) by means of the steam coils. If the tank and heating system have been properly designed, this temperature should be secured by a steam pressure of 25 or 30 lb. After the refined asphalt is melted, flux which has previously been heated to about 90° C (194° F) in another kettle is run into the tank, the contents of which are then thoroly agitated until of absolutely uniform consistency. From 3 to 10 hr, depending upon the efficiency of the agitation, are required to thoroly flux the asphalt. If air agitation is employed reactions, such as attend the blowing process, are induced to some extent with a resultant

change in the characteristics of the asphalt cement. For this reason steam agitation is often used. With steam, however, considerable care must be exercised to use only dry steam and to prevent the injection of any condensate, within the pipe, which may have resulted from previous uses. Steam agitation should not, of course, be started until the temperature of the charge is sufficiently high to prevent condensation, or otherwise serious foaming will result. In any event, at the end of the fluxing process it is advisable to finish the agitation with air injected thru the pipes which have been used for steam in order to prevent condensation within the pipes upon cooling and a resulting inflow of asphalt which will clog the perforations. It is seldom necessary or advisable to conduct the fluxing process at a temperature of over 163° C (325° F), but in no case should 205° C (400° F) be exceeded. The flux should contain but little material which is volatile at the fluxing temperature as it is difficult to control the consistency of an asphalt cement which is constantly losing appreciable quantities of its lighter hydrocarbons by volatilization. As in petroleum refining, the consistency of the asphalt cement is gaged and controlled by means of the penetration test. The approximate proportions of the refined asphalt and flux necessary to produce an asphalt cement of desired penetration are first experimentally determined by laboratory tests. In the large scale fluxing operation somewhat less than the calculated amount of flux is first used and the penetration of the resulting asphalt cement is then taken. From this penetration the additional flux required may, as a rule, be closely estimated. It has been found that, under average conditions, when making such corrections, 1 lb of flux per 100 lb of refined asphalt will soften a product of 40 or 50 penetration from two to four-tenths of a millimeter penetration. Prolonged agitation and heating tend to harden an asphalt cement or lower its penetration. At a paving plant where large batches are being slowly drawn from, it is therefore necessary to keep close watch on such change in consistency and to add more flux from time to time as needed. The physical and chemical characteristics of an asphalt cement produced by fluxing will partake of the nature of both refined asphalt and flux to some extent altho it resembles most closely the constituent which predominates. Some, but not all of the properties, are additive and may be foretold from analyses of the constituents and a knowledge of the proportions in which they are to be used. Fluxes which are suitable for one asphalt will not always produce satisfactory asphalt cements from another asphalt. In general, the heavier the flux the more is required to produce an asphalt cement of given penetration from a given refined asphalt. Light fluxes prepared from a given petroleum, as a rule, produce asphalt cements less susceptible to temperature changes than do the heavier fluxes produced from the same petroleum, but they are apt to be more volatile at elevated temperatures.

Fluxed Native Asphalts. The refined native asphalts almost invariably have to be fluxed before they are suitable for use in highway engineering In sheet asphalt construction, the preparation of asphalt cements from refined native asphalts is usually undertaken at the paving plant. Some of the asphalts are, however, fluxed by the producer and sold as asphalt cements ready for use in other types of construction. For the sake of comparison the characteristics of refined Trinidad Lake asphalt and a Trinidad asphalt cement prepared with a heavy asphaltic flux are shown in Table XII. As compared with the refined asphalt it will be noted that the asphalt cement contains the higher percentage of bitumen and lower

percentage of mineral matter. This is due to the fact that the flux is almost pure bitumen. Where the composition of a refined native asphalt is as uniform as Trinidad asphalt, it is possible to determine with reasonable accuracy from the characteristics of the asphalt cement not only the characteristics of the flux which has been used but also the percentage of flux. This is done from those properties which are usually additive, such as specific gravity, solubility in carbon disulphide and solubility in naphtha. According to Forrest (20c), from 21 to 60 parts of commercial flux available in 1914 to 100 parts of refined Trinidad Lake asphalt are required to produce an asphalt cement of 50 penetration at 25° C (77° F). From the analysis given above it is evident that about 60 parts of a heavy residual flux to 100

parts of refined asphalt have been used in the preparation of the asphalt cement. The analyses of a refined Bermudez Lake asphalt and a Bermudez Lake asphalt cement are shown in Table XIII, while in Table XIV a Cuban asphalt and a Cuban asphalt cement are given. As neither refined Bermudez or Cuban asphalts are of as uniform composition as refined Trinidad asphalt, it is not always an easy matter to determine from an examination of these asphalt cements the characteristics of the flux and the amount which has been used. According to Forrest (20c), from 9 to 28 parts of the fluxes commercially available in 1914 to 100 parts of refined Bermudez asphalt were required to produce an asphalt cement of 50 penetration at 25° C (77° F).

Fluxed Oil Asphalts. Refined asphalts produced by the straight distillation of petroleum, are, if too hard for a given use, fluxed to asphalt cements of any desired penetration by use of a petroleum residuum flux as in the case of refined asphalts. If the flux has been prepared from the same type of petroleum and shows but little loss by the volatilization test at 163° C (325° F), it will produce an asphalt cement from the refined asphalt which is almost identical with that which would have been obtained by straight distillation of the petroleum to the same consistency. The use of different types of fluxes will of course produce from the same refined asphalt, asphalt cements of somewhat different characteristics.

Cut-Back Asphalt Cements are those which have been fluxed with a distillate. The distillate may be a light volatile fraction or a heavy non-volatile fraction. The former is more generally used, as the common reason for employing a distillate flux is to temporarily soften or liquefy an asphalt cement which has the proper penetration or consistency for a given purpose but which for one reason or another cannot readily be used in its original state in the type of treatment or construction selected. Such cut-back asphalt cements should, after use, rapidly lose the distillate flux by volatilization and acquire and maintain their original consistency. Fluid cut-back asphalt cements possess certain very desirable characteristics for surface treatment as compared with fluid petroleum residuums. They

are sometimes manufactured for use with cold stone in the preparation of bituminous concrete consisting of a coarse aggregate. In under-surface work, however, the distillate flux does not usually volatilize as rapidly as desirable. Cut-back asphalt cements may usually be identified by their relatively low flash point, high percentage loss by volatilization at 163° C (325° F) and lower temperatures, and marked hardening of the material. Because of their low flash point they should be carefully heated before use. The fluid cut-back asphalt cements prepared with a heavy non-volatile distillate are not essentially different from the fluid non-volatile petroleum residuums. They usually possess or develop but little cementitiousness. The characteristics of two cut-back asphalt cements prepared with volatile distillate fluxes, the one fluid and the other very viscous, are given in Table XV.

Cut-back asphalt cements of any degree of fluidity may be prepared by adding the proper amount of suitable distillate. When gasoline is used as a cutting-back medium in considerable amount, it should preferably be a heavy gravity gasoline produced from an asphaltic petroleum and consisting mainly of polymethylene hydrocarbons which are much better solvents for the asphalt cement than are paraffin gasolines. The paraffin gasolines are only partial solvents and their use may result in the precipitation of the solid asphaltic hydrocarbons, thus producing a material which lacks in uniformity and in which the ultimate cementing value may be poor, altho the original asphalt cement was of good character.

ROCK ASPHALTS

23. Production of Rock Asphalts

The Occurrence of Rock Asphalts has been covered to some extent under native asphalts, and statistics of their production and importation by the United States for 1910 to 1913 inclusive are given in tables in Art. 17,

The production for various European countries is included in the figures for all semisolid and solid native bituminous materials. As the true native asphalts occur to only a limited extent in Europe, these figures mainly represent bituminous rock or rock asphalt. Italy and France are the two largest producing countries and Germany ranks third. Owing to the comparatively small amount of bitumen which they contain and to the high cost of transportation but little European rock asphalt finds its way into the United States, altho some has been imported for use in the paving industry, and was employed in this connection as early as 1876 at Washington, D. C. Considerably earlier in the 19th century rock asphalts were used in the construction of sidewalks and pavements in the European countries but its success in this connection was not pronounced until 1854. The term asphalte is commonly applied to these products in Europe but not in the United States. Rock asphalt usually consists of limestone or sandstone impreganted with maltha or asphalt, its origin and formation being similar to these materials except that as mined the bitumen constitutes only a relatively small percentage of the product obtained. Those in common use contain from 6 to 14% bitumen. One of the earliest discovered and operated deposits is located at Val de Travers, Neufchatel, Switzerland. This deposit of bituminous limestone was worked as early as 1712. In France, large deposits of bituminous limestone occur at Seyssel, Autun, Aumance, Ain, Gard, Puy-du-Dôme, Levagny, Mons and Haute-Savoie, of which the Seyssel deposit was opened about 1797. In Italy, bituminous limestone occurs in paying quantities, and on the Island of Sicily at Ragusa, Syracuse, Catania and Mazzarelli. Both bituminous limestone and bituminous sandstone occur in Germany, the principal deposits being at Lobsann in Alsace and at Limmer and Vor Wohle. Other European deposits are located in Spain at Maester; in Russia at Syzran, Samara and on the island of Tchelekin; in Greece near Marathonopolis, and at a number of localities in Turkey. Deposits are found widely distributed over the United States and Canada, the more important being located in the States of Texas, Oklahoma and Kentucky.

Mining Rock Asphalts. The general methods of mining or quarrying rock asphalt are not unlike those for ordinary rock quarrying. As some rock asphalts become adhesive and gummy in warm weather, making it difficult to drill holes for the blasting charge, the quarrying may be carried on in underground tunnels except in cold weather, when it may be blasted. The exact method of mining varies somewhat with the character of the rock asphalt as some, particularly the bituminous sandstones, are loose-grained and friable and almost wholly dependent upon the bitumen to hold the individual mineral particles together, while others are hard and dense, the rock being merely saturated with bitumen.

Preparation of Rock Asphalt. After coming from the quarry the rock asphalt is crushed or broken into small lumps which may either be shipped as such or else further reduced. It is usually crushed between toothed or grooved steel cylinders known as roll crushers but sometimes by centrifugally operated flail or hammer crushers. In order to obtain a product suitable for direct use in highway work it is sometimes necessary to combine two or more grades of rock asphalt containing different percentages of bitumen. By this means the proper percentage of bitumen for the particular character of aggregate may be secured. The blending or mixing is often carried on in a large revolving mixing cylinder or kettle in which the rock is heated to a temperature of about 100° or 125° C (212° or

257° F.) Sometimes a rock asphalt is enriched by the addition of asphalt and, if the natural bitumen is harder than desirable, a petroleum residuum or flux is used to soften it to suitable consistency.

Transportation of Rock Asphalt. The harder grades of rock asphalt may be most conveniently shipped in the lump form, in which case, however, they usually have to be crushed or prepared for use upon arrival at their destination. They are commonly transported by rail or as ballast in vessels. It is seldom economy, however, to ship them long distances. If shipped in pulverized or prepared form the mass of originally loose particles is apt to congeal and compress under its own weight so that in unloading it has to be handled with pick and mattox and afterwards warmed before it may be separated to its original prepared condition. Upon long storage it almost invariably congeals to a solid mass. The crushed bituminous sandstones are usually easier to handle than the limestones, owing to their coarser texture.

24. Characteristics of Rock Asphalts

Bituminous Limestones are more or less pure limestones or calcium carbonate impregnated with bitumen. They may be of a semicrystalline, conglomerate or chalky nature, and contain varying percentages of sand and other mineral substances. The purer carbonate rocks crush down to a fine powder, each particle of which appears to be impregnated with bitumen. This powder is often of a brownish color and appears dry, altho it may contain as high as 15 or 16% bitumen. Under compression, and especially at an elevated temperature, the better grades congeal to form a dense tough mastic composed of very fine mineral particles cemented together with the bituminous cement. The bitumen may vary in consistency from a soft maltha to a hard brittle asphalt. It is, however, a difficult matter to recover the bitumen so as to positively identify its original consistency. This is due to an almost unavoidable hardening which it undergoes during the laboratory extraction and recovery process. The percentage of bitumen varies widely but in the better grades of commercial products is seldom less than 7 or 8%. Analyses showing the percentage of various constituents present in typical European bituminous limestones as given by Howard (22) are shown in Table XVI. It should be remembered, however, that the percentage of bitumen present in rock from different parts of the same deposit often varies considerably.

An analysis, as made by the U. S. O. P. R., of a typical specimen of an important American bituminous limestone deposit occurring in Uvalde County, Texas, is given below. This product is a shell limestone or conglomerate impregnated with a hard asphalt as shown by the characteristics of the recovered bitumen. In this material, which after preparation has been used quite extensively in highway construction, accumulations of almost pure bitumen are frequently found in the small shell pockets of the conglomerate.

Analysis of Texas Bituminous Limestone

Specific gravity	2.173
Soluble in CS_2 (total bitumen)	13.10%
Insoluble matter	86.90%
	100.00%

Examination of recovered bitumen:

Specific gravity 25°/25° C (77°/77° F)	1.091
Penetration at 25° C (77° F)	10
Melting point	86° C (187° F)
Bitumen insoluble in 86° B naphtha	49.25%
Fixed carbon	16.51%
Ash	0.48%

Bituminous Sandstones are usually of much coarser texture than bituminous limestones and, while the bitumen permeates the natural rock, it appears rather to coat the mineral particles than to impregnate them. In their preparation for use the sand grains are not necessarily crushed to produce a mastic with the bitumen, but may be merely broken down or partly separated. A prepared bituminous sandstone may therefore have the general appearance of a sheet asphalt paving mixture altho the mineral particles seldom show the grading considered most desirable for sheet asphalt work. The percentage of various constituents of a Spanish rock asphalt as given by Howard (22) is shown in the following analysis:

Analysis of Maester Bituminous Sandstone

CRUDE TARS

25. Formation of Tars

Sources of Tar. The term tar has been applied to many black viscous materials consisting mainly of hydrocarbons and their derivatives, whether produced by destructive distillation or not. Thus viscous residues produced by the preliminary fractional distillation of petroleums, which residues are later distilled to coke in a separate still, are sometimes known as tar to the petroleum refiner. As generally accepted, however, the term is confined to bituminous distillates produced by the destructive distillation of almost any organic material providing that, upon being themselves subjected to fractional distillation, these distillates will yield semisolid or solid residues known as pitches. Tars thus differ materially from bituminous distillates produced by fractional distillation, as the latter cannot again be fractionally distilled so as to produce semisolid or solid residues. The sources of tar which are of particular interest in highway engineering are bituminous coal and petroleums. Both are largely used in the manufacture of illuminating gas and the former is also consumed in immense quantities in the manufacture of coke. Both gas and coke are produced by the destructive distillation of these substances and the tar is obtained as a by-product. Other substances of a non-bituminous nature usually accompany the formation of tar and often occur as impurities in the crude tar. As in the case of other crude bituminous materials the impurities are more or less completely removed by refining processes.

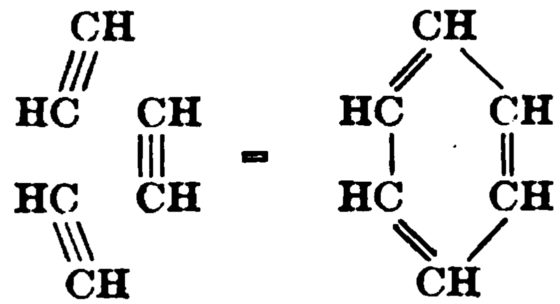
Formation of Tar Hydrocarbons from Coal. The high temperatures involved in destructive distillation are particularly favorable to the forma-

tion of liquid and solid hydrocarbons belonging to the unsaturated cyclic and polycyclic series. The proportion and, to a considerable extent, the character of such hydrocarbons produced from coal vary with the character of the coal distilled and the particular conditions of time, temperature and pressure which attend the process. In general, however, hydrocarbons of the benzene, C_nH_{2n-6}, naphthalene, C_nH_{2n-21}, and anthracene, C_nH_{2n-18} series predominate, altho members of many of the other unsaturated open chain and cyclic series are also found in varying proportions. Coals themselves are complex mixtures of hydrocarbons, the molecular composition of which is little understood. It is, however, definitely known that coal tar is not a simple mixture of the volatile constituents of the coal, but that it is the product of complex chemical reactions that take place during the process of carbonization or destructive distillation. The probable character of the reactions involved are more or less speculative, but it is reasonable to suppose that, at the very high temperatures employed the volatile hydrocarbons of the coal dissociate into radicals such as CH_3—, $CH_2 =$ and $CH \equiv$. If nascent or atomic carbon, $C \equiv$, and hydrogen H—, are also split off, as seems probable, the formation of almost any of the hydrocarbons actually present in tars may be readily explained. The primary hydrocarbons formed contain one or two carbon atoms to the molecule and therefore consist of methane, CH_4, ethylene, C_2H_4, and acetylene, C_2H_2, first members of their respective series. Under suitable conditions these hydrocarbons react, break down or polymerize during the distillation process to form members of other, and often more complicated series of hydrocarbons. The general nature of the initial reactions, many of which are reversible, may be shown as follows:

$$
\begin{array}{lrcl}
 & 2CH_4 & = & C_2H_6 + H_2 \\
\text{or} & 2CH_4 & = & \underline{C_2H_2} + 3H_2 \\
 & C_2H_6 & = & C_2H_4 + H_2 \\
\text{or} & 2C_2H_6 & = & \underline{C_2H_2} + 2CH_4 + 2H_2 \\
 & C_2H_4 & = & C_2H_2 + H_2 \\
\text{or} & 2C_2H_4 & = & \underline{C_2H_2} + C_2H_6
\end{array}
$$

It will be seen that there is a general tendency to form acetylene which readily polymerizes to form the volatile liquid benzene, which may be graphically shown as follows:

$3C_2H_2$ or



The formation of naphthalene and anthracene thru the reaction of benzene and acetylene are given in the following equations:

$$C_6H_6 + 2C_2H_2 = C_{10}H_8 \text{ (naphthalene) } + H_2$$
$$2C_6H_6 + C_2H_2 = C_{14}H_{10} \text{ (anthracene) } + 2H_2$$

These reactions explain why tars produced by the destructive distillation of entirely different original substances, such as coal and petroleum, may

be and often are similar in chemical and physical properties. Whatever the exact nature of these reactions may be, it is certain that at very high temperatures an ultimate decomposition of the vaporized hydrocarbons takes place with the formation of free carbon and free hydrogen. While the resulting hydrogen is found in the permanent gases, a large proportion of the carbon is deposited in the tar as an inert impurity. At lower tem-

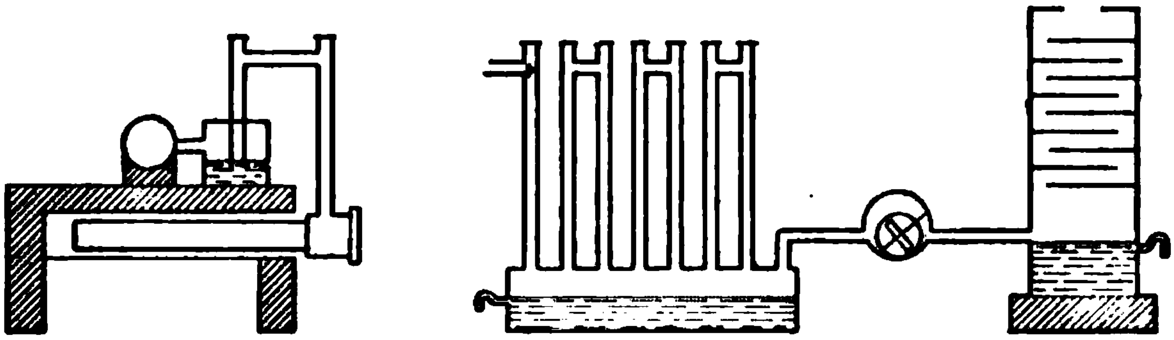


Fig. 12. Coal-Gas Plant

peratures ultimate decomposition of the vaporized hydrocarbons becomes less, so that tars produced at relatively low temperatures contain less free carbon than those produced at the higher temperatures. If the substance originally subjected to destructive distillation contains oxygen, sulphur or nitrogen, these elements are usually found in the tar as oxygen, sulphur or nitrogen derivatives of some of the tar hydrocarbons. Practically all bituminous coal contains oxygen and some of this oxygen during destructive distillation combines to form phenols and cresols which appear in the tar.

Manufacture of Coal Tar. The general principles of coal tar manufacture are the same whether conducted in a gas-house with horizontal, inclined or vertical retort, or in a by-product coke-oven. While the details of plant apparatus and operation vary somewhat, and therefore the character of the resulting tar, the general plan of operation may be illustrated by the gas-house process with horizontal retort. A diagram of the principal parts of such a gas-house plant is shown in Fig. 12. In the manufacture of illuminating gas, bituminous coal is first placed in horizontally set semi-oval fire-clay retorts about 8 ft long, 15 in high, and 18 in wide at the bottom. A battery of six or eight of these retorts set together in a brick furnace constitutes a bench, and a number of benches built together is called a stack. The retorts are charged from one end and after charging all openings are closed with the exception of a vertical stand-pipe extending upwards from the front and connecting by a bridge with a vertical dip pipe. The dip pipes from all of the retorts in a stack connect with a long covered trough running the entire length of the stack and known as the hydraulic main. The hydraulic main is partly filled with water which serves as a seal for the outlet of each dip pipe. Upon heating the retorts, which have been partly filled with coal, volatile hydrocarbons are produced and these hydrocarbons in the gaseous state react within the retort to form the types of products treated of in the preceding paragraph. As the gases are evolved they pass thru the standpipe, bridge and dip pipe into the hydraulic main where a considerable proportion of the liquefiable hydrocarbons condense under water. As the tar collects it is drawn off by various ingenious devices upon reaching a certain height in the hydraulic main. The gas from the hydraulic main passes thru a pipe to the condenser which usually consists of a series of vertical cast-iron pipes

connected at the top and opening at the bottom into an iron box, which is divided by transverse partitions extending nearly to the bottom and dipping into water or former condensates, so that the gas is forced to pass thru all of the pipes. The condenser is cooled either by air or water so that the gas is slowly brought to a temperature of 50° C (122° F). More of the liquefiable hydrocarbons condense here. The gas is drawn thru the condenser and forced thru the remainder of the purifying apparatus by means of a mechanical device called the exhauster, which serves to prevent back pressure upon the retort. From the exhauster, the gas passes thru a tar extractor or scrubber, consisting of a tower fitted with numerous perforated horizontal plates or other device, where the last traces of tar vapor are condensed and removed by friction. From this point on the process of gas manufacture ceases to be of interest so far as the production of tar is concerned. The finished gas consists of a mixture of hydrogen and incondensable hydrocarbons such as methane, while coke or relatively pure carbon and any mineral matter present in the original coal remains in the retort. Approximately 60% of all the tar produced condenses in the hydraulic main, 15% in the condenser, and 25% in the scrubber. As would naturally be expected, the heavier and more viscous liquid hydrocarbons condense first in the hydraulic main, and the lighter and more fluid products in the scrubber. As the tar is drawn off from the various parts of the plant, however, it is usually run into a common well or storage tank where it is allowed to settle for some time in order to separate it as completely as possible from water and other impurities. The character of the tar itself is largely influenced by the temperature employed in the destructive distillation of the coal, which lies between 850° and 1540° C (1562° and 2804° F). Up to 970° C (1778° F) is commonly considered low temperature, from 970° to 1100° C (1778° to 2012° F) medium temperature, and above 1100° C (2012° F) high temperature. The yield of tar per ton of coal varies greatly, but in American practice averages from 7½ to 10½ gal. In general, the higher the temperature of destructive distillation the greater the yield. As the temperature of distillation increases, the percentage of free carbon in the tar increases and also the percentage of hydrogen in the gas. This is due to the more complete decomposition of the hydrocarbons at high temperature. The viscosity of the tar also increases with the temperature of distillation. The effect of temperature and other conditions is further considered under the various classes of tar in Art. 27.

Formation of Tar Hydrocarbons from Petroleum. From the preceding paragraph it is evident that the formation of the hydrocarbons occurs under entirely different conditions of temperature, pressure and time than the formation of petroleum hydrocarbons. Thus tars are produced rapidly at high temperatures and low pressures, while, as shown in Art. 13, petroleums are formed very slowly at low temperatures and high pressures. If, however, petroleums or petroleum products are themselves subjected to high temperatures and low pressures, the hydrocarbons crack or dissociate in much the same way as the coal hydrocarbons, with the formation of ultimate products quite similar and in many respects identical with the products of the destructive distillation of coal.

Manufacture of Water-Gas Tar. Water-gas tar is a by-product incidentally manufactured during the process of carburetting water-gas by means of destructively distilling or cracking at high temperatures certain classes of petroleum or petroleum products known as gas oils. The straight water-gas is produced by the reaction between steam and incandescent car-

bonaceous material, such as coke or anthracite coal, without the production of hydrocarbons. This reaction is commonly written $C + H_2O = CO + H_2$. As no hydrocarbons are formed in this process there can be no formation of tar. The straight water-gas, which consists of a mixture of carbon monoxide and hydrogen, burns with a non-luminous flame and, in order to make it a true illuminating gas, it is necessary to enrich it by the introduction of gaseous hydrocarbons. This is usually accomplished with one of the distillates of petroleum known as gas oil which is cracked in contact with the water-gas by what is known as the carburetting process. The gas oil is thus converted into permanent gaseous hydrocarbons and liquefiable hydrocarbons which ultimately condense to produce tar. The origin of water-gas tar is therefore petroleum. A diagram of the principal parts of a carburetted water-gas plant is shown in Fig. 13. In the process of water-gas manufacture the coke or anthracite coal is first heated to redness in a large cylindrical metal chamber called the generator. Air is then admitted to the generator thru a blast pipe and passes thru the incandescent fuel with which it reacts to form producer gas. The hot producer gas passes out of the generator into the top of a second cylindrical chamber called the carburettor where it meets a blast of air from another pipe connected with the source of air supply. Here it is partly oxidized and the resulting heat of combustion raises the temperature of the checkerwork of brick which fills the carburettor. The unconsumed gas and products of combustion then pass from the bottom of the carburettor into the bottom of a third and taller cylindrical chamber called the superheater which is also filled with a checkerwork of brick. Here the unconsumed gases are entirely oxidized by air admitted thru another blast pipe. The products of combustion then escape thru a stack valve at the top of the superheater. This process is only preliminary to the actual manufacture of water-gas and is continued just long enough to bring the fuel in the generator to a bright red heat and the brick checkerwork in the carburettor and superheater to proper temperature to cause cracking of the petroleum hydrocarbons later introduced. When this is accomplished, steam is admitted to the generator thru a small pipe, all of the air blasts are shut off and the stack valve on the superheater closed. Plain water-gas is formed in the generator by the action of the steam upon the incandescent fuel and passes into the carburettor, where it meets a spray of gas oil introduced thru a pipe at the top. The oil is here gasified and carried by the water-gas into the superheater, where it is cracked or broken up into permanent hydrocarbon gases by the high temperature of the brickwork and also into heavier hydrocarbons which later condense as tarry products during the process of gas purification. The carburetted water-gas passes thru a pipe near the top of the superheater to condensers and scrubbers similar to those described under the MANUFACTURE OF COAL TAR.

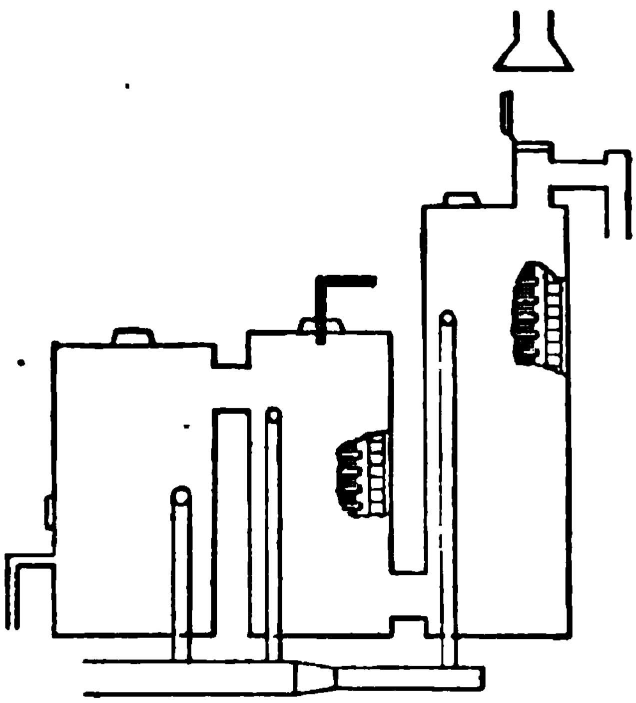

Fig. 13. Carburetted Water-Gas Plant

Here the tar is deposited and is afterwards run into storage tanks. The character of the tar is considerably influenced by the character of oil which is used, and as in the case of coal tar, by the temperature at which it is produced. The yield of tar varies from 2 to 18% by volume of the oil used for carburetting. For the ordinary petroleum distillate gas oils it will average about 10%. While the average temperature of cracking or distillation of carburetted water-gas manufacture is higher than for coal-gas manufacture, the maximum temperature is lower and for this reason, as well as the fact that cracking is produced in an atmosphere rich in hydrogen, the water-gas contains a lower percentage of free carbon than coal tar. A greater proportion of light condensable hydrocarbons is also produced so that the crude water-gas tar is much more fluid than crude coal tar.

26. Production of Tars

Production of Tar in the United States. Statistics relative to the production of tar in the United States are neither as complete nor available as those for the production of petroleum. The production is so widely distributed and there are so many small plants which do not keep an accurate record of their tar manufacture that reliable information is difficult to secure. In the early days of gas manufacture, tar was considered as a waste product and proved to be a source of nuisance not only to the manufacturer but to the public, as it was often run into rivers and streams, causing pollution of the water. Later it was discovered that many valuable products could be obtained by its fractional distillation and chemical treatment. From a waste product it therefore gradually became a valuable by-product and is now accumulated and sold by most gas manufacturers who do not use it as fuel in their manufacturing processes. Statistics of the production of tar were first compiled by the United States Government in 1898, and since then reports on the subject have been issued at irregular intervals. In these reports coal tars are divided into two groups those produced at gas works and those produced at by-product coke-oven plants. The tars produced and sold at water-gas and oil-gas works are considered collectively. The production of these tars from 1904 to 1913 for the years recorded is given in Table XVII.

Table XVII.—Production and Sale of Tar in the United States, 1904–1913, in Gallons

Year	Coal Tar			Water-Gas and Oil-Gas Tar	Total
	Gas-House	Coke-Oven	Total		
1904	41 726 970	27 771 115	69 498 085	....	....
1905	43 642 189	36 379 854	80 022 043	....	....
1907	49 581 965	53 995 795	103 577 760	....	....
1908	58 541 220	42 720 609	101 261 829	9 168 834	110 430 663
1912	40 489 855	94 306 583	134 796 438	33 930 273	168 726 711
1913	....	115 145 025	....	....	....

A comparison of the production for 1908 and 1912 is particularly instructive as showing the general trend of development. From these figures it will be noted that in 1908 gas plants were the most important source of

supply of coal tar, while in 1912 the production from this source had notably decreased. This was in large measure due to the increasing use of carburetted water-gas and the introduction of carburetted water-gas manufacture at many plants where coal-gas was still produced. A very great increase in the production of water-gas tar for this period is shown, as water-gas tar constituted by far the largest proportion of tar produced from petroleum or oil. It is seen that the production of water-gas tar for 1912 closely approached that of gas-house coal tar, while in 1908 it was of rather minor importance. The most remarkable development is however shown by by-product coke-oven tar, the production of which was increased by over 50 000 000 gal. A continued marked increase is shown for 1913. Coke-oven tars are in general admirably adapted to the manufacture of road and paving materials. Their production in the United States dates only from 1893, when twelve by-product coke-ovens were constructed at Syracuse, N. Y. By the end of 1912 over 5000 by-product coke-ovens were in operation, and the future production of tar from this source promises to become of even greater relative importance. Immense quantities of coke have been and are being coked in the old beehive type of oven, in which no attempt is made to recover any portion of the coal which is volatilized during destructive distillation. In beehive coke-oven practice, all tar hydrocarbons which are formed are wastefully burned at the outlet of the oven. Some idea of the tremendous loss in tar production by this process may be obtained by the relative amount of coal coked and tar produced therefrom in the by-product coke-ovens. In 1913 the by-product ovens produced 115 145 025 gal of tar from 17 089 700 tons of coal. During the same year 52 150 400 tons of coal were coked in beehive ovens without recovery of tar. Upon the same basis of yield as for the by-product coke ovens, this represents a loss of nearly 350 000 000 gal of tar or over twice the total production of all classes of tar for the preceding year. The encouraging advance of by-product coke-oven practice over that of the beehive oven is shown by the fact that in 1908 of the total coke produced that from by-product ovens amounted to about 16%, while in 1912 it exceeded 27%. A corresponding decrease in percentage of total coke production from beehive ovens occurred during that year. In regard to the actual total production of all types of tar in the United States, it is of interest to note that the gallonage for 1912 amounted to less than 2% of the total production of petroleum in the United States for that year.

Production of Tars in European Countries. The tar industry did not assume any considerable proportions until a number of years after the erection of the first coal-gas works in England in 1798. The first public gas works made their appearance in London in 1813, in Paris in 1815, and in Berlin in 1826. It was not until 1838, however, that the utilization of tar and tar products began. By 1883 it is estimated that England was producing between 70 000 000 and 90 000 000 gal of coal tar, Germany about 17 000 000, and France about 15 000 000 gal. Belgium and Holland were then producing considerably smaller amounts. Meanwhile, various types of by-product coke-ovens began to come into quite general use. By 1900 it is estimated that the entire world was producing about 450 000 000 gal of coal tar and oil tars. England has always maintained the lead in production for the European countries, altho Germany has been most active in developing the utilization of tar products in general. The approximate production of all gas-house tars and coke-oven tars for the United Kingdom from 1900 to 1907 is given in Table XVIII. A comparison of these

Table XVIII.—Approximate Production of Tar in the United Kingdom, 1900–1907, in Gallons

Year	At Gas Works	At Coke-Oven Works	Total
1900	138 000 000	10 000 000	148 000 000
1901	140 000 000	11 000 000	151 000 000
1902	141 000 000	14 000 000	155 000 000
1903	142 000 000	16 000 000	158 000 000
1904	142 000 000	18 000 000	160 000 000
1905	145 000 000	27 000 000	172 000 000
1906	150 000 000	39 000 000	189 000 000
1907	....	48 000 000	....

figures with those of Table XVII shows that as far back as 1905 the United Kingdom was producing over twice as much as the United States and more than the United States produced in 1912. It is estimated that in 1907 Germany produced some 180 000 000 gal of tar. From the figures given it will be seen that the four leading tar producing countries of the world are England, Germany, the United States and France, in the order named.

Transporation and Storage of Crude Tar. At gas works crude tars are sometimes collected and stored in underground tanks or wells and sometimes in the bottom of large gas holders. Here much of the water and water-soluble impurities separate by gravity so that the crude tar sold to the tar refiner has been partially dehydrated by sedimentation. The crude tar is transported to the refineries by various means. When the refinery is located close to the gas or coke-oven works the tar may sometimes be run thru pipe lines, but this method of transportation is not satisfactory for long distances as in the case of petroleum transportation because many tars become extremely viscous at low temperatures. From the smaller gas plants tar is often transported in railroad tank cars of approximately 10 000 gal capacity. Whenever possible, however, water transportation is employed and the tar is shipped in tank barges of from 25 000 to 300 000 gal capacity. Upon reaching the refinery the tar is run by gravity or pumped into storage tanks similar to those used for the storage of petroleum. Tank cars, tank barges and the storage tanks are often equipped with steam coils for the purpose of warming the tar if necessary to facilitate its rapid handling. At a modern refinery the storage tanks range from 250 000 to 2 000 000 gal capacity. Where large quantities of tar from a single source of supply are handled, the larger tanks are employed. Where tars of varying characteristics are obtained from many sources, the smaller tanks are used to keep the different types and grades separate. The storage tanks are cylindrical in shape and set on end, usually upon a concrete base. They are constructed of steel with the exception of the roof, which is generally of wood, as the vapors from the tar are particularly corrosive to steel but non-injurious to wood. The wooden roofs are waterproofed to keep out rain water. Outlet cocks are placed on the sides of the tanks at varying heights in order to drain off water which may rise to the surface of the crude tar during storage. The crude tar is piped directly to the dehydrating plant or still for refining.

27. Classification of Tars

General Characteristics. There are many classes of tars which vary greatly in character, among which may be mentioned those produced by the destructive distillation of wood, peat, lignite, bituminous coal, bituminous shale, petroleum, animal fats, vegetable fats, rosin, bone, molasses and alcoholic residues. As previously stated, those of particular interest in highway engineering are coal tars and petroleum tars, of which latter group the carburetted water-gas tars are of most importance. The three groups which should receive special consideration are gas-house coal tars, coke-oven tars and carburetted water-gas tars. All of these tars are similar in composition but variations in the relative proportions of the individual constituents cause wide variations in their physical and chemical properties. The ultimate analysis of these tars is not greatly different from crude petroleums, altho in the case of coal tars oxygen and nitrogen are always present in greater amount. Their specific gravity usually varies from 1.05 to 1.30 and slightly higher and their viscosity generally increases with their specific gravity. The lighter varieties are thin, oily, brown fluids, while the heavier tars are very viscous, black, sticky substances. They all have a rather unpleasant acrid odor quite distinct from the odor of crude petroleum. The odor of coal tar can usually be distinguished from that of water-gas tar by the presence of phenolic or carbolic vapors. Moreover, crude coal tar always contains as an impurity water carrying ammoniacal salts in solution, known as ammoniacal liquor, while water-gas tar does not, owing to the absence of appreciable quantities of nitrogen in the oil from which it is produced. All crude tars carry variable quantities of light volatile hydrocarbons which evaporate upon exposure. When freed from water and water-soluble impurities, many of them still hold appreciable quantities of free carbon suspended in a very finely divided state. This material is insoluble in carbon disulphide and runs from a few tenths of one per cent in water-gas tars to 30% and over in coal tars produced at high temperature. As they have been produced primarily as distillates they yield little or no ash upon ignition. Crude tars as delivered at the refinery seldom contain over 10% of water unless they carry a very high percentage of free carbon, in which case water to the extent of 20% or more may be retained by the tar. The very fluid low carbon tars tend to separate from water much more readily and may contain 1% or less. They are powerful solvents for nearly all bituminous materials, including petroleums and asphalts but in general and unlike petroleums their solvent action decreases somewhat as their specific gravity increases. As a rule, their coefficient of expansion varies inversely with their specific gravity, but according to Weiss (44) lies between 0.000305 and 0.000375 per degree C. Their specific heat usually lies between 0.3 and 0.4. Further characteristics of the more important classes and groups of tars are given in succeeding paragraphs.

Gas-House Coal Tars are tars produced by the destructive distillation of bituminous coal primarily for the manufacture of gas. The object of the gas manufacturer is to obtain as much gas as possible from a given quantity of coal and for this reason the temperature of distillation is carried very high. As practiced in the United States this tends to produce high carbon tars. As the quality of gas produced at high temperatures is deficient in illuminating value, it is often enriched with carburetted water-gas. The manufacturer, therefore, frequently produces both coal tar and water-gas tar which he runs into a common storage tank. When such practice

is followed, the resulting tar is not a gas-house coal tar but a mixture of tars. There are three general types of retort used in gas manufacture, known as horizontal, inclined, and vertical. The horizontal retort is almost exclusively used in the United States, altho some few plants operate the other types. In European countries the use of vertical retorts is rapidly increasing, especially in England and Germany. Gas-house tars produced in the different types of retorts vary greatly in character owing to variations in the resulting conditions of distillation. In general, inclined retorts produce tars containing a lower percentage of free carbon than do the horizontal retorts, and the vertical retorts produce quite low carbon tars, which in this respect resemble most of the coke-oven tars. Figs. 14, 15, and 16 are diagrams showing the relative proportions of certain constituents in typical crude gas-house coal tars free from water, which have been produced from horizontal, inclined and vertical retorts. In these diagrams the area below the line *a a* represents soft refined tar residue of about 60° C (140° F) melting point produced by distilling off a sufficient amount of the more volatile constituents. The white area A represents the saturated hydrocarbons present in the distillate which are unattacked by concentrated sulphuric acid. Area B represents the unsaturated hydrocarbons in the distillate, and area C the oxygenated hydrocarbons or phenols and cresols removed with a

Fig. 14. Horizontal Retort Tar

Fig. 15. Inclined Retort Tar

Fig. 16. Vertical Retort Tar

solution of caustic soda. Area D shows the amount of heavy pitch bitumen composed almost entirely of unsaturated hydrocarbons, and area E represents the amount of free carbon. It will be noted that all of the free carbon is shown in the pitch residue and that it therefore constitutes a larger percentage of the residue than of the crude tar. The effect of free carbon in refined tars is treated in Art. 28. It will be noted that the horizontal and inclined retort tars show a much higher percentage of free carbon than does

the vertical retort tar. In all cases the percentage of saturated hydrocarbons is very small. The percentage of tar acids is largely dependent upon the amount of oxygen present in the coal from which the tar was produced but is also a function of the temperature of distillation and in all cases constitutes an appreciable proportion of the distillate. While these diagrams give a general idea of the relative characteristics of the three principal types of gas-house coal tars, the fact should not be lost sight of that the exact temperature and other conditions of distillation exert a marked influence upon tar produced from exactly the same coal. Thus two tars produced from the same coal and in the same type of retort but at different temperatures may vary greatly. From the horizontal gas-house retort as commonly fired, tars containing less than 20% free carbon are the exception rather than the rule. In the early days of the coal-gas industry, however, when high illuminating value of the coal gas itself was a prime requisite and enriching methods were not in vogue, the gas-house coal tars usually contained a very much lower percentage of free carbon and were of considerably lower gravity.

Coke-Oven Tars are those produced by the destructive distillation of bituminous coal in ovens or retorts designed primarily for the manufacture of large quantities of coke. Such ovens, which are constructed for the recovery of tar and other volatile constituents of the coal, are called by-product coke-ovens. There are many designs of coke-ovens, a number of which are in common use. At the close of 1913, 5688 by-product coke-ovens had been constructed and 504 were under construction. Of these ovens by far the largest number are the United Otto, Semet-Solvay, and Koppers types. Other types are known as the Otto-Hoffmann and the Didier ovens. By-product coke-ovens are very much larger than gas-house retorts. The original Semet-Solvay ovens were 30 ft long, about 16 in wide, and 5 ft 8 in high, with a charging capacity of over 4 tons of coal. The original Otto-Hoffmann ovens were somewhat larger and had a charging capacity of about 5½ tons. Many of the modern ovens are over 36 ft long, 26 in wide, and nearly 12 ft high, and have a charging capacity of from 12 to 16 tons of coal. These ovens are built of fire-clay brick and a number set together in a brick framework over a furnace. Because of the large charges of coal which they hold, the distillation process is slower than in gas manufacture, and as the main object is the production of coke, the temperature of distillation is usually kept lower than for gas manufacture. This results in the production of tars containing medium or low percentages of free carbon. The percentage of free carbon in the various types of coke-oven tars produced in the United States in

Table XIX —Free Carbon in Coke-Oven Tars of the United States

Type of Oven	Percent of Free Carbon		
	Minimum	Maximum	Average
Koppers	2.81	3.95	3.38
Semet-Solvay	4.04	9.00	6.74
United Otto	5.26	12.55	9.00
Otto-Hoffmann	8.62	14.69	12.16
Otto-Hoffmann and United Otto (mixed)	11.51	13.52	12.51
United Otto and Rothberg (mixed)	17.17	17.17	17.17

1911 are given in Table XIX. These figures are for the crude tars free from water.

The typical characteristics of an average coke-oven tar are shown in diagram in Fig. 17. The lettered areas in this diagram represent the same constituents as described for gas-house coal tars under Figs. 14, 15, and 16. In different coke-oven tars the relative proportions of constituents, of course, vary within certain limits as indicated by the percentage of free carbon in Table XIX. As compared with Fig. 14 it will be seen that in general coke-oven tars contain a somewhat lower percentage of pitch residue than do the horizontal gas-house retort tars. Owing to the very much lower percentage of free carbon (area E), however, the coke-oven tar really contains a higher percentage of heavy pitch bitumen as shown by area D. As the pitch bitumen constitutes the true cementing medium it is evident that a given quantity of refined coke-oven tar residue will go farther as a cementing medium than will the same quantity of refined horizontal gas-house retort tar. The inclined and vertical retort tars shown in Figs. 15 and 16 are similar to the coke-oven tars in this respect. It is seen that coke-oven tars like the gas-house tars contain but a small percentage of saturated hydrocarbons (area A) but are mainly composed of unsaturated hydrocarbons, the proportion of which in the distillate is shown by area B. Like the gas-house tars, they contain an appreciable quantity of tar acids (area C).

Water-Gas Tars are those produced by the cracking or destructive distillation of petroleum or petroleum products in the carburetion of water

Fig. 17. Coke-Oven Tar

Fig. 18. Water-Gas Tar

gas. They are thin, oily liquids usually having a specific gravity of between 1.000 and 1.100. They are produced in an atmosphere rich in hydrogen and carbon-monoxide and it is probable that the excess of hydrogen is partially responsible for some of the differences between water-gas tars and coal tars. One of these differences is a greater proportion of methyl derivatives of the unsaturated cyclic compounds which predominate in all tars. As the original oils contain little or no nitrogen and oxygen, nitrogen and oxygen derivatives of the hydrocarbons are almost entirely lacking in water-gas tars. For the same reason, crude water-gas tars do not contain ammoniacal liquor as an impurity. The sulphur derivatives may, however, occur as in the case of coal tars. The relative proportions of various constituents in a typical water-gas tar are shown diagramatically

in Fig. 18, which is directly comparable with Figs. 14 to 17 inc, showing four types of coal tars. As compared with the diagrams of the coal tars it will be noticed that the percentage of soft refined tar residue as indicated by the area below the line *a a* is considerably lower, amounting to about 57% against the 87% for the horizontal retort tar and 70% for the coke-oven tar. This is due to the higher percentage of volatile oils and very much lower percentage of free carbon. The free carbon, as shown by area E, constitutes about 1% of the refined tar residue and less than 1% of the entire tar. It is rare for crude water-gas tar to contain over 2% of free carbon, and sometimes less than 0.1% is present. This of course means a high percentage of heavy pitch bitumen as shown by area D, altho the total percentage of refined tar or pitch residue is comparatively low. The amount of saturated hydrocarbons, altho small as shown by area A, is found to be slightly greater than for the coal tars. This is not always true, however. In general, with a given type of gas oil, the more efficiently the carburetting process is run in the manufacture of water-gas the lower the yield of saturated hydrocarbons in the tar produced. This is explained by the fact that fractional distillation of the gas oil will yield comparatively high percentages of condensable saturated hydrocarbons; mild cracking less, and ultimate cracking or destructive distillation but little if any. It will be noticed that area C, the oxygenated hydrocarbons, is entirely lacking in the above diagram. This is one of the distinguishing characteristics of water-gas tar because of the absence of phenols and cresols or tar acids. The water-gas tar distillates are therefore almost entirely composed of unsaturated cyclic hydrocarbons.

Other Tars. Among the tars of minor importance may be mentioned BLAST-FURNACE TARS and OIL-GAS TARS. The former are sometimes recovered from blast furnaces in which coal is used as a fuel in the reduction of the ore. The production of blast-furnace tars is almost negligible as compared with the other types of tars which have been described. They are, however, members of the coal-tar family altho often quite different in character as they contain a much higher percentage of saturated hydrocarbons, and their specific gravity is much lower owing to the comparatively low temperature at which they are produced. Unlike the other tars, they may yield upon ignition as high as 5 to 7% ash due to the presence of fine mineral matter which is blown over into the condensers from the blast furnace. Oil-gas tars as distinguished from water-gas tars are produced in the manufacture of straight oil gas. There are a number of processes for producing illuminating gas directly from petroleum or petroleum products, all of which are dependent upon cracking the oil vapors in especially constructed retorts so as to form permanent gases of high illuminating value. Tar condensates are incidentally produced and in some of the processes the tar itself is again cracked for the production of more gas so that in the end little but hydrocarbon gases and free carbon or coke are produced. It is unlikely that either oil-gas tars or blast-furnace tars will ever be used to an appreciable extent for the manufacture of bituminous road and paving materials.

REFINED TARS

28. Distillation of Tars

Tar Stills. Stills for refining tars vary in size and shape fully as much as petroleum stills. They are constructed of steel and set in a brick framework, being protected from direct fire by means of a fire arch. The most

commonly used tar stills in Europe are vertical cylinders with a dome-shaped top and concave bottom as shown in Fig. 19. Their capacity is usually 2000 or 3000 gal. The top is provided with a manhole and an inlet pipe for charging. A large curved vapor pipe at the top of the dome leads the volatile products to a coil condenser. A draw-off pipe is located near the bottom and leads directly to a cooling tank or smothering chamber. The bottom of the tank is made concave to facilitate the distribution of heat thruout the charge. The still is provided with a thermometer pocket or opening near the top for thermometer or pyrometer. It is equipped with interior pipes branched and suitably perforated so that steam or air may be injected into the charge of tar during distillation and thus facilitate the removal of the heavier oils without recourse to unduly high temperatures. The condensing coil is placed in a large tank of water which may be kept cool for the condensation of the light volatile distillates and be warmed, if necessary, to prevent clogging with solid naphthalene if the tar distilled runs high in that constituent. The vertical type of still is used to a limited extent in the United States and is sometimes constructed with a convex instead of concave bottom. It may be either wholly or partly incased in brickwork. The general tendency in American practice, however, is to make use of long cylindrical horizontally set stills similar in general design to the commonly used petroleum still. The modern horizontal tar still averages about 10 000 gal capacity but sometimes runs as high as 20 000 gal. The details of construction are so similar to petroleum stills which have been described in Art. 19, that Fig. 8 may serve as a general illustration for both. The tar stills are fitted with devices for steam- or air-agitation and a by-pass is sometimes placed in the vapor line to deflect the flow of tar from the condenser should frothing occur, as the tar refiner is even more seriously bothered by the presence of water in the product distilled than is the petroleum refiner. This by-pass leads to a spue tank which is capable of holding the entire contents of a still if necessary. The stills are placed in the open and a number are often set in a single brick framework to form a battery. The modern condensers are of similar design to those used in connection with petroleum stills but often discharge into deep narrow rectangular tanks or pans which are allowed to fill until the total distillate which they contain shows the gravity at which a cut is to be made. The pan is then discharged into the proper storage tank. The stills are fitted with small draw-off pipes thru which samples of the residuum may be taken and tested during the distillation process. A large draw-off leads to the cooler or smothering chamber so that at the end of a distillation the charge of residuum may be run off by gravity or, if the still is at a lower elevation than the cooler, it may be forced over by steam or air pressure. The coolers are large iron tanks exposed on all sides so as to obtain as quick cooling as possible. The cooling, however, often requires a long time before it is safe to run the residual into open barrels. In some cases the coolers are provided with steam coils so as to keep the residual at any desired temperature for further handling. The coolers are provided with a weighed cover or automatic relief to take care of any explosion which may result from the presence of air in the cooler at the time the hot residue is run in.

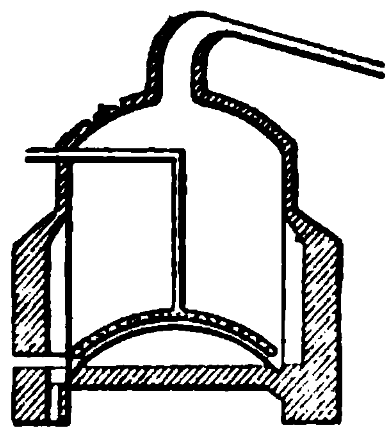

Fig. 19. Vertical Tar Still

For the softer residues which may be shipped in tank cars, recourse is often had to air or steam pressure as a means of transporting them thru pipe lines, which are sometimes steam jacketed in order to prevent possible clogging by too rapid cooling of the tar. By means of these lines the refined tar may, if desired, be blown directly from the still to the tank car or tank wagon.

Tar Refining. As it is practically impossible to remove all water from crude tars by sedimentation, they are sometimes run thru special dehydrating devices before charging them into the still (see Art. 9, DEHYDRATION. The water may be removed by distillation but it is a slow and expensive process, as great care has to be exercised to prevent foaming and a long time is required to coax the water off without bringing with it the entire contents of the still. This is particularly true of high carbon tars in which the free carbon appears to tenaciously retain the water. Moreover, the specific heat of the tar is only about 0.3 or 0.4 so that much extra heat is required to remove the water by distillation. Dehydrating devices, however, usually leave a small amount of water in the tar and considerable trouble is experienced from even this small quantity which may amount to only a few tenths of one per cent. After charging, the contents of the still are carefully heated until the vapor temperature is about 105° or 110° C, (221° or 230° F) when all the water has passed off with the light distillate. This point is usually indicated by the cessation of a peculiar noise within the still, known as the rattles, which occurs as the last of the water is being removed and is produced by condensation of the water at the top of the still, from which it falls back into the more highly heated residuum, thus causing a series of small explosions as it is suddenly converted into steam again. After all water has been removed distillation proceeds quietly and without trouble provided steam or air agitation is used. This is particularly necessary in the case of tars containing a high percentage of free carbon, owing to the tendency of the carbon to deposit on the bottom of the still and produce a heavy coating of coke. Agitation with air does not produce as pronounced an effect with tars as with petroleums, there being but little chemical reaction induced between the oxygen of the air and the tar hydrocarbons at the temperature of distillation. The exact method and extent of distillation depend upon just what products the tar refiner is primarily working for. In most cases the tar producer does not distill his own tar but sells it to the refiner, who may purchase from a great many sources of supply. When this is the case the tar refiner often has a variety of tars of different characteristics upon which to work and the selection or blending of two or more tars before distillation is fully as important as the method and extent of distillation when it is desired to produce refined products having given characteristics. In the preparation of refined chemicals such as drugs and dyes, of which there are an immense number, from tar distillates, the European countries are far in advance of the United States. This is particularly true of Germany, which country disposes of large quantities of tar products to the United States. As a result the European tar refiner often works primarily for quantity and quality of valuable distillate and in so doing distills his tar to a hard brittle pitch residue. In incidentally producing residues of any desired consistency, he then fluxes or cuts back the brittle residue with the least valuable distillate or distillate product which he has available. In other words, his residues are of secondary importance and their quality for use in highway engineering may suffer thereby. The American refiner, on the other hand, as a rule works

primarily for residues or refined tars and prepares comparatively few refined products from his distillates. This is shown by the fact that altho the production of crude tar in the United States is vastly more than sufficient to produce all of the refined chemical products which it consumes, it nevertheless annually imports millions of dollars' worth of such products but little or no residuals. This is shown by the following importation statistics for 1913 as given by Parker (32).

Table XX.—Coal-Tar Products Imported into the United States, 1913

Material	Value	Duty
Salicylic acid	$ 2 969	$ 613
Alizarin and other colors or dyes	1 493 840	Free
Aniline salts	323 420	4 034
Colors or dyes not specially provided for	7 253 788	2 176 136
Preparations not colors or dyes	702 721	131 268
Products not medicinal, such as benzol, etc	1 186 090	11 678
Total	$10 962 828	$2 323 729

The methods of American refiners in the manufacture of tar residuums are of particular interest from the standpoint of highway engineering and Fig. 20 serves to illustrate the general practice followed in the manufacture of straight residuals and certain crude distillates. As distillation proceeds the residue in the still becomes more and more viscous. Samples are withdrawn and tested from time to time until the desired consistency has been secured. In the case of quite fluid residuals viscosity tests are made. For the semi-solid and solid residues, the float and melting point tests are largely used. As in the case of petroleums, the residual, after being discharged from the still, is usually a finished product and requires no further treatment. For some purposes, however, cut-back products are manufactured, but in such cases the original distillation is seldom carried to the production of a hard brittle pitch residue. Residues of various consistency are generally sold as dust layers, carpeting mediums, cements for use in bituminous macadam construction and coarse aggregate bituminous concrete, and also as fillers. Distillates are only of interest

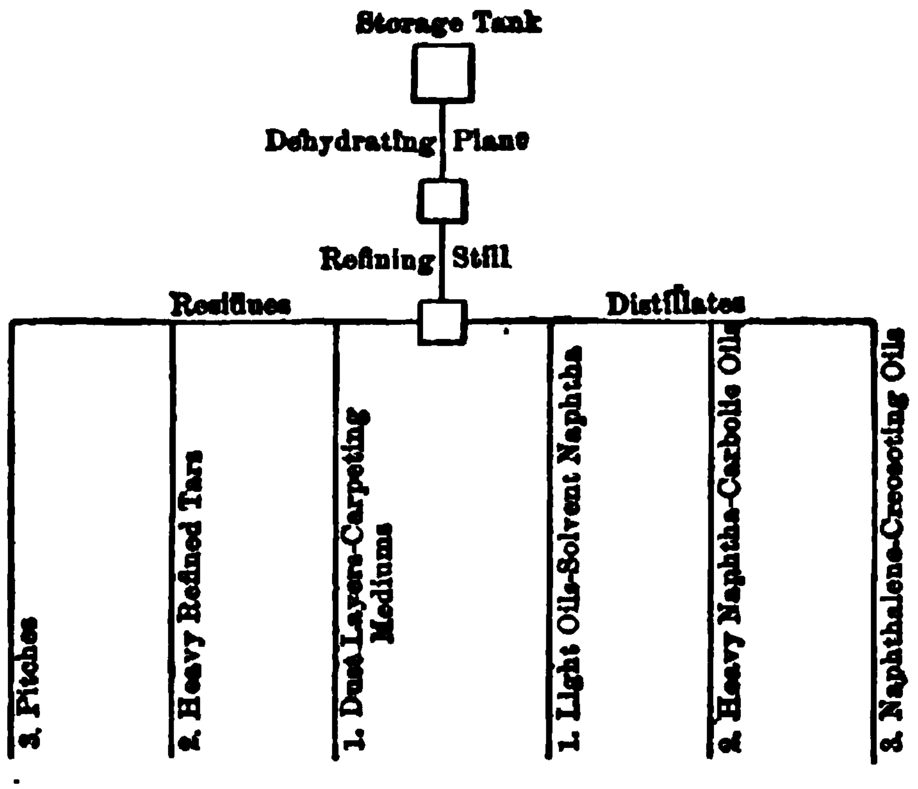

Fig. 20. Distillation of Tar

from the standpoint of highway engineering when used as creosoting oils for wood block and structural timber or when used for cutting back the tar residues. The lighter distillates are usually further refined by redistillation and acid purification for the production of various grades of benzol, toluol, solvent naphtha, etc. The next heavier distillates are often worked for the recovery of naphthalene, and in the case of coal tars for phenol or carbolic acid and cresols. Distillates for creosoting purposes are considered in the following subsection. None of the distillates are ordinarily used as dust layers as in the case of petroleums. In some cases either during or after distillation a relatively small amount of either fluid petroleum residuum or asphalt is combined with the tar residuum with which it readily fluxes. Such materials are then known as tar-asphalt products and if properly prepared may show certain desirable characteristics which would not be possessed by the straight distilled tar residue. For further details and principles governing distillation, see Art. 10.

Free Carbon in Tars exists in the form of finely divided amorphous black particles resembling soot or lampblack. These particles are held in suspension in the tar and will not readily settle out even if the tar is very fluid. They are insoluble in carbon disulphide and are therefore not bitumen. If filtered from the bitumen with the aid of this solvent the free carbon is found to be a dry black powder entirely lacking in cementitiousness. Ultimate analysis indicates that it is not, however, pure carbon but probably a mixture of hydrocarbons very rich in carbon, which have been produced by a very advanced stage of cracking of the vaporized hydrocarbons within the retort or superheater during the original formation of the tar. For all practical purposes, however, it may be considered as carbon and as an inert impurity in the tar bitumen. It is non-volatile at ordinary distilling temperatures and for this reason always remains in the residue of a tar distillation. It thus necessarily constitutes a larger proportion of any tar residue than of the original tar from which the residue was produced. As a very high percentage of free carbon is not considered desirable in refined tars commonly used in highway engineering, those crude tars which originally carry a high percentage of free carbon cannot well be utilized in the manufacture of such products unless mixed in suitable proportions with a low carbon crude tar prior to distillation. If both low and high carbon tars are available to the tar refiner, he is able by judicious mixing to obtain a combination which upon subsequent distillation will yield a refined tar containing less than the maximum limit of free carbon which has been set. Knowing the percent of distillate which will have to be removed in order to produce a residue of desired consistency, the percentage of free carbon in the refined tar may be closely approximated from the percentage present in the material distilled. If, however, the tar is badly cracked or locally overheated during distillation, additional free carbon will be formed. As all tars originally contain some free carbon, however, it is impossible from its determination in the finished product to determine whether or not cracking has taken place during distillation as in the case of petroleum products. While chemically inert, free carbon has a decided effect upon certain physical characteristics of the tar in which it occurs. It increases the gravity of a tar and also its viscosity or apparent consistency to a marked extent. It is quite possible to remove free carbon from a tar by passing it in a heated and fluid state thru a filter press. This process is not as a rule commercially possible in the manufacture of refined tars for use in highway engineering, but if carried out

the filtered tar is found to have a lower gravity and to be much more fluid than before filtration. This latter fact has a most important bearing on the proper selection and specification of refined tars containing a considerable amount of free carbon as the consistency of the actual tar bitumen is a most important consideration. In a general comparison of low and high carbon tars the following facts are of interest to the highway engineer. For refined tars of the same degree of hardness those of low free carbon contents have greater inherent binding strength than those of high carbon contents. In refined tars whose bitumen is of the same degree of hardness, those high in free carbon have a greater inherent binding strength than those low in free carbon, but the binding capacity of the former is lower because of the lower percentage of bitumen present. The waterproofing value of high carbon tars is in general less than that of low carbon tars. A high percentage of free carbon tends to retard absorption of the tar bitumen by porous surfaces. When a tar is exposed in comparatively thin films free carbon has little or no effect in retarding volatilization of the lighter bituminous constituents. In certain classes of tar aggregates free carbon may serve as a filler and add to the mechanical strength of the aggregate, but finely divided mineral matter, which may be incorporated in any desired amount, is more satisfactory in this connection. In general it is considered desirable that a tar dust layer should not contain over 8% free carbon, that a tar carpeting medium should not contain over 15% free carbon, and that for bituminous macadam and bituminous concrete construction a refined tar should not contain over 20% free carbon. There is, however, some difference of opinion in this connection.

Naphthalene in Tars. Naphthalene, $C_{10}H_8$, frequently occurs in tar in larger quantity than any other one hydrocarbon, and for this reason it exerts an appreciable influence upon the physical and chemical properties of the tar. In the pure state it exists in white flakey crystals or scales melting at 79° C (174° F) and having a boiling point of 218° C (424° F). It has a characteristic odor commonly familiar in moth balls and is extremely volatile. It volatilizes far below its boiling point and from crude tars distills to a considerable extent with the aqueous vapors and also with the light tar oils. Even at ordinary temperatures it volatilizes slowly from both crude tars and refined tars in which it is present. No satisfactory method has as yet been devised for its quantitative determination in tars, but its presence in appreciable quantities is readily detected by its crystallization from certain fractions obtained by distilling the tar. In some tars it occurs to such a large extent that almost the entire distillate solidifies or crystallizes upon cooling. In the manufacture of straight residual refined tars for use in highway engineering some of the naphthalene is removed during distillation. A considerable proportion, however, usually remains behind in the residue. The presence of this naphthalene exerts a marked influence upon the consistency of the tar, and as it is a volatile constituent its effect in this connection is of considerable interest. From its nature it cannot be considered as a binding constituent, but, altho it is solid, it may combine with and serve as a flux for those hydrocarbons which are directly responsible for the cementitiousness of tars. Thus by heating together a quantity of naphthalene and a hard tar pitch, it is possible to produce a soft and almost fluid product. In this connection it has been found that the fluxing value of naphthalene for hard tar pitches is somewhat greater, altho quite similar to the heavier tar distillates free from naphthalene or other crystallizable solids. This is true until the mixture becomes so sat-

urated as to cause the naphthalene to precipitate. For the harder tar pitches the addition of very small percentages of naphthalene produces a more marked increase in fluidity than for originally softer pitches. On the other hand, where naphthalene is present beyond its point of saturation, it decreases the fluidity of the product at temperatures below its melting point but at higher temperatures it continues to increase the fluidity of the product. The conclusions to be drawn from the above facts are that refined tars containing a high percentage of naphthalene, altho the lighter tar oils may be absent, may be expected to harden rapidly upon exposure thru loss of the naphthalene by volatilization. This is particularly true when the refined tar is used for surface treatment. Naphthalene may be entirely eliminated from a tar by distillation to a hard pitch residue and cutting-back such residue to desired consistency with a heavy non-volatile naphthalene free tar distillate, but this practice is seldom followed in American refineries. Where rapid hardening after use is not desired, as in the case of refined tars for bituminous concrete construction, a low naphthalene tar is preferable to one containing a high percentage of naphthalene.

29. Refined Tar Products

Crude and Residual Tar Dust Layers. Crude tars are sometimes used as dust layers. The majority of crude coal tars are, however, too viscous for successful cold application and have to be combined with distillates or very fluid tars in order to make them applicable for such use. Water-gas tars and some coke-oven tars may be applied cold in their crude or partially dehydrated state. It is customary, however, to subject tars to some process of refinement before marketing them. High carbon tars are totally unsuited for use as dust layers. The majority of tar dust layers are therefore manufactured from low carbon crudes. In order to so use tars containing as high as 5% free carbon, it is not unusual to have them combined with a small amount of water, which increases their fluidity. Partly dehydrated coke-oven tars combined with water-gas tars may be made to serve this purpose. As crude water-gas tars are very fluid and contain a low percentage of free carbon, they may be distilled to remove their more volatile oils without increasing their viscosity to such an extent that cold application is impossible. Semisolid residual tars may also be fluxed or cutback with a large amount of tar distillate to produce dust layers. Refined tars are also emulsified in some cases in much the same way as petroleums (see Art. 21) for use in dust laying. Tar emulsions have not, however, been used in the United States to any extent. The tar refiner usually has so many different types and grades of tars which he can blend to produce the product he wishes to manufacture that it is often a difficult matter to identify the origin of a manufactured product. The primary function of tar dust layers is identical with that of petroleum dust layers. Owing to the fact that they tend to volatilize and harden more rapidly, however, their excessive use is not as serious a matter as is the case with the petroleum dust layers. They should be sufficiently fluid to apply cold by means of a pressure distributor at a rate of not over ¼ gal per sq yd. Their repeated use may result in the formation of a thin, comparatively hard superficial coat or bituminous carpet. They are often used to advantage in the surface treatment of an old bituminous macadam, as they tend to enrich the seal coat and prolong its life. They are black in color and usually have a strong odor of light oils and naphthalene.. The analyses on opposite page are typical of tar dust layers. The first analysis is that

of a dust layer produced from a water-gas tar by distillation of the more volatile constituents. The second is of one produced from a low carbon coal tar and shows the presence of both water and light oils. The water is largely responsible for the low specific viscosity of this material as compared with the first sample, altho its precentage of pitch residue or heavy tar hydrocarbons is higher. Its specific gravity and percentage of free carbon indicate a coke-oven tar.

Table XXI —Tar Dust Layers

	(1)	(2)
Specific gravity 25°/25° C (77°/77° F)	1.120	1.149
Specific viscosity (Engler) 50 cu cm, 40° C (104° F)	14.0	10.9
Soluble in CS_2 (total bitumen)	99.05%	95.05%
Organic matter insoluble (free carbon)	0.90%	4.89%
Inorganic matter insoluble (ash)	0.05%	0.06%
	100.00%	100.00%
Distillation percent by volume:		
Water	0.0%	1.7%
Oil distillate to 110° C	0.0%	0.9%
Distillate 110° to 170° C	0.7%	2.5%
Distillate 170° to 270° C	23.7%	18.4%
Distillate 270° to 300° C	13.1%	4.6%
Pitch residue above 300° C	62.5%	71.9%
	100.0%	100.0%

Refined Tar Carpeting Mediums are usually straight distilled residual tars too viscous to apply cold. When heated, however, they should become sufficiently fluid to apply uniformly over a road surface by means of a pressure distributor at the rate of not over ½ gal per sq yd. They ordinarily possess considerable cementitiousness and harden rather rapidly after application as compared with the residual carpeting mediums prepared from petroleum. Like other carpeting mediums, their function is first of all to adhere to the road surface and then hold in place the covering of fine aggregate with which they should combine to form a bituminous carpet. If used in excess they are apt to produce a mechanically unstable carpet owing to their original soft consistency. Applied at the proper rate they harden sufficeintly after application to produce a stable carpet. The initial hardening which is desirable is apt to continue, however, until the carpet becomes so hard as to wear away rather rapidly under traffic. This is particularly true of those products which contain a high percentage of the lighter oils or an excess of naphthalene or free carbon. For carpet work, this general tendency to harden even too much is preferable to not hardening sufficiently. The very qualities which make residual tars suitable as carpeting mediums make them less desirable for seal coat work on bituminous macadam or bituminous concrete pavements. For such purpose a harder bituminous material is preferable as it will adhere to the newly laid bituminous concrete and can be used of originally desirable consistency. Seal coats should therefore harden as little as possible after use. In some cases petroleum or asphalt products are combined in relatively small proportion, usually not over 15%, with tar carpeting mediums in order to reduce the tendency to harden too much. The characteristics

of two typical tar carpeting mediums are shown in Table XXII. The first material is a tar-asphalt preparation as evidenced by the dimethyl sulphate test, and has been prepared from a water-gas tar. The second material is a coal-tar product as shown by the relatively high percentage of free carbon which, however, is not excessive. It contains no petroleum or asphalt product as shown by the dimethyl sulphate test.

Table XXII.—Tar Carpeting Mediums

	(1)	(2)
Specific gravity 25°/25° C (77°/77° F)	1.158	1.210
Float test at 50° C (122° F)	85 sec	45 sec
Soluble in CS_2 (total bitumen)	98.50%	85.05%
Organic matter insoluble (free carbon)	1.45%	14.93%
Inorganic matter (ash)	0.05%	0.02%
	100.00%	100.00%
Distillation percent by volume:		
Water	0.0 %	0.0 %
Distillate to 110° C	0.0 %	0.0 %
Distillate 110° to 170° C	0.3*%	0.0 %
Distillate 170° to 270° C	6.8*%	14.5†%
Distillate 270° to 300° C	17.9*%	8.0‡%
Pitch residue above 300° C	75.0 %	77.5 %
	100.0%	100.0%
Melting point of pitch residue	65° C (149° F)	74° C (165° F)
Dimethyl sulphate test on fraction above 300° C	part insoluble	all soluble

* Distillate free from precipitated naphthalene.
† Distillate contained about three-fourths its volume precipitated naphthalene.
‡ Distillate practically solid.

From the above results it will be seen that altho the second material is originally softer or shows a lower float test than the first, its tendency is to harden much more rapidly owing to the higher percentage of distillate to 170° C (338° F) and the presence of a large amount of naphthalene.

Bituminous Cements from Tars. Because of their tendency to harden after use and their susceptibility to temperature changes, the residual tars used in bituminous macadam and bituminous concrete pavements are usually much softer than either the residual petroleums or fluxed native asphalts used in the same types of construction. This is admissible when the aggregate is coarse because of the high cementitiousness of the soft semisolid tar residues. For fine aggregates where mechanical stability is dependent upon the hardness of the bituminous cement, tars are not generally used except perhaps for sidewalk construction. For the coarser aggregate pavements the same grade of tar used in the construction of the wearing course proper is also commonly used as a seal coat. Altho such a seal coat is apt to harden more rapidly than desirable in the case of the bituminous macadam, the underlying thick films of tar tend to enrich and prolong the life of the seal coat. In bituminous concrete construction, however, there is not the same excess of bitumen in the underlying course and for this reason an asphalt seal coat is sometimes employed when a refined tar is

used in the concrete proper. The characteristics of bituminous cements prepared from a water-gas tar, a coke-oven tar and a gas-house coal tar are shown in Table XXIII. Altho these tars are of similar consistency, as shown by the float test, it will be noted that, as in the case of crude tars, the residual water-gas tar shows the lowest percentage of free carbon and the residual gas-house coal tar the highest. The specific gravity of these tars increases with the percentage of free carbon. All of the materials show

Table XXIII.—Bituminous Cements from Various Tars

Tar	Water-Gas	Coke-Oven	Gas-House
Specific gravity 25°/25° C (77°/77° F)	1.172	1.215	1.258
Float test at 50° C (122° F)	158 sec	140 sec	170 sec
Soluble in CS_2 (total bitumen)	99.12%	86.60%	70.37%
Organic matter insoluble (free carbon)	0.83%	13.38%	29.60%
Inorganic matter insoluble (ash)	0.05%	0.02%	0.03%
	100.00%	100.00%	100.00%
Distillation percent by volume:			
Water	0.0 %	0.0 %	0.0 %
Distillate to 110° C	0.0 %	0.0 %	0.0 %
Distillate 110° to 170° C	0.7 %	0.3 %	0.0 %
Distillate 170° to 270° C	6.2 %	5.4 %	9.4 %
Distillate 270° to 300° C	16.0 %	12.9 %	6.5 %
Pitch residue above 300° C	77.1 %	81.4 %	84.1 %
	100.0 %	100.0 %	100.0 %
Melting point of pitch residue	65° C (149° F)	71° C (160° F)	85° C (185° F)

a very low percentage of ash, and the percentage of total bitumen is therefore almost entirely dependent upon the amount of free carbon present. All of the residuals have been prepared at sufficiently high temperatures to remove the more volatile oils as shown by the results of distillation. The relation of total distillate to pitch residue is found to vary somewhat but the ratio of total distillate to actual bitumen in the pitch residue will, upon calculation, be found to be nearly the same. Pitch fillers for stone and block pavements are manufactured from tars by distilling and blowing the residue to the desired melting point. They are often quite hard and brittle and contain a high percentage of free carbon, show a high specific gravity and a melting point of 45° C (113° F) or higher. They are much more susceptible to temperature changes than are the blown petroleum or asphalt products prepared for the same purpose.

CREOSOTING OILS

30. Manufacture of Creosoting Oils

Classification of Creosoting Oils. The term creosote was originally applied to certain constituents of wood tar. Later it was extended to cover the oxygenated hydrocarbons or cresols found in the distillates of coal tar. Those distillates, particularly the heavy distillates rich in oxygenated hydrocarbons, were then known as creosote oils. Creosote oils from coal tar

have for many years been extensively used to impregnate wood for structural uses, the process of impregnating being known as creosoting. The term creosoting oil is now commonly applied not only to the creosote distillate oil but to a variety of other bituminous materials which are used to impregnate wood. Creosoting oils are of particular interest in highway engineering with regard to the impregnation of wood paving block. Their use in this connection dates back to a pavement laid at Galveston, Texas, in 1873. Creosoting oils which are used in the preservation of wood blocks may be classified as (1) heavy distillates of coal tars and water-gas tars; and (2) residual tars and oils containing tar residues. Petroleum oils have also been used to a limited extent in the impregnation of wood for structural purposes.

Preparation of Creosoting Oils. Distillate creosoting oils are obtained mainly from coal tars but also from water-gas tars by the process of fractional distillation such as described in Art. 28. They vary considerably according to the cuts made during distillation and the character of tar distilled. During distillation of the crude tar a cut is usually made after the removal of practically all oils boiling as high as 170° C (338° F). The heavier oils then begin to distill and the creosoting oil may consist of the entire distillate obtained during the remainder of the distillation process. It is evident that the extent to which distillation is carried will materially affect the characteristic of the creosoting oil produced by this means from a given tar. Sometimes the heavy distillates from a number of distillations of different tars will be mixed together to produce the creosoting oil. Two types of tar may also be mixed prior to distillation and thus produce a creosoting oil of somewhat different character than would have been produced by the distillation of either alone. Sometimes intermediate cuts or fractions may be made during distillation and certain of these fractions worked for the recovery of desirable constituents such as naphthalene, anthracene, etc, after which the remaining oils are run back with the rest of the creosoting oil distillate. The second class of creosoting oils mentioned in the preceding paragraph may be prepared in a variety of ways. Where very fluid crude tars are available, such as water-gas tars and certain coke-oven tars, they may be distilled for the removal of water and some of the lighter oils and the residues still be sufficiently fluid to use as creosoting oil. If too viscous they may be thinned to the desired degree of fluidity with a small amount of heavy oil obtained from another distillation. In the case of low carbon tars distillation may be carried to the formation of a pitch residue and the pitch then fluxed with a large amount of heavy tar distillate to produce a creosoting oil. Creosoting oils containing residual products may therefore be either straight fluid residues or mixtures of oils and residues.

31. Characteristics of Creosoting Oils

Function and General Characteristics. In the manufacture of creosoted wood block, creosoting oils are ordinarily used in connection with the impregnation of southern yellow pine, Norway pine, Douglas fir, or tamarack. The oils should be sufficiently fluid to manipulate properly and at the temperature of impregnation, somewhat under 121° C (240° F), should suffer no chemical change or decomposition. They should adequately waterproof the block when present to the extent of from 14 to 20 lb per cu ft. They should preferably be as slightly volatile as possible under the conditions to which the block is subjected, and when used to the extent

necessary for waterproofing should not ooze out of the wood or bleed in warm weather. They should in addition possess sufficient antiseptic properties to prevent decay of the wood from the action of fungus or other growth. Their permanent waterproofing value is perhaps the most important consideration in so far as the life of the pavement is concerned and this is of course dependent to some extent upon their tendency to remain in the wood and not volatilize.

Tar Distillate Oils have been more extensively used in the treatment of wood block than have the oils containing tar residues. A large proportion of the distillate oils used in the United States is imported from Europe. They differ in certain respects from the average American oil. Considerably over 60 000 000 gal of creosoting oils are annually consumed by the United States. The importation of creosoting oil to the United States, as shown by statistics of the Census Bureau, was as follows for the fiscal years 1910 to 1914 inclusive, ending June 30.:

1910	36 719 782 gal
1911	45 499 838 gal
1912	50 319 736 gal
1913	63 997 602 gal
1914	59 271 677 gal

The characteristics of typical domestic and foreign distilled oils available in large quantities, as given by Forrest (20b), are shown in Table XXIV.

Table XXIV.—Distilled Creosoting Oils

Type	Domestic	Foreign	Coke-Oven
Specific gravity 15.5° C (60° F)	1.08	1.04	1.09
Free carbon	0.0 %	0.0 %	0.0 %
Tarry matter	1.3 %	0.7 %	10.0 %
Tar acids	7.0 %	13.6 %	trace
Solid naphthalene	....	18.0 %	....
Distillation:			
Distillate to 170° C	0.42%	0.70%	1.60%
Distillate 170° to 205° C	4.50%	1.50%	2.40%
Distillate 205° to 235° C	51.95%	35.20%	19.80%
Distillate 235° to 270° C	22.01%	32.60%	15.20%
Distillate 270° to 315° C	10.99%	20.00%	11.60%
Residue above 315° C	10.13%	10.00%	49.40%
	100.00%	100.00%	100.00%
Character of residue	soft	soft	soft
Insoluble in dimethyl sulphate	0.0 %	0.0 %	0.0 %
Paraffin scale	0.0 %	0.0 %	0.0 %

It will be seen that all of the distilled oils have a gravity somewhat greater than one. They may or may not carry a high percentage of naphthalene. Both naphthalene and the tar acids are quite volatile constituents, and from this standpoint are undesirable if present in excessive amounts. None of the oils contains free carbon as they are fractional distillates. The absence of petroleum products is shown by the absence of paraffin scale and material insoluble in dimethyl sulphate. All three oils yield but little distillate below 205° C (401° F). The percent of residue above 315° C (599° F) is shown to be much higher for the coke-oven tar oil than for the other two. This varies markedly, however, in different oils produced from the same tar, according to the extent of the original tar distillation. For an oil distilled from a given tar the percent of residue above 315° C (599° F)

usually increases with the specific gravity but this is not necessarily so for oils produced from different tars, as shown by the following analyses of a coal tar distillate creosote and a water-gas tar distillate creosote as given by Forrest (20*b*).

Table XXV.—Coal Tar and Water-Gas Tar Creosote Oils

Type	Coal Tar	Water-Gas Tar
Specific gravity 15.5° C (60° F)	1.098	1.072
Distillate to 235° C	15.0%	1.5%
Distillate 235° to 315° C	29.0%	15.0%
Residue above 315° C	56.0%	83.5%
	100.0%	100.0%

Creosoting Oils Containing Tar Residues are almost invariably heavier than the pure distillate oils and may usually be distinguished from the former by the presence of free carbon and the production of a hard pitch residue when distilled to 315° C (599° F). As an excessive amount of free carbon tends to prevent proper impregnation of the wood, only low carbon tar residues can be present to any considerable extent in this class of creosoting oils. The characteristics of typical creosoting oils containing tar residues which are available in large quantities, as given by Forrest (20a), are shown in Table XXVI.

Table XXVI.—Creosoting Oils Containing Tar Residues

Type	From Coke-Oven Tar	From Water-Gas Tar
Specific gravity 15.5° C (60° F)	1.16	1.13
Free carbon	5.3 %	0.6 %
Tarry matter	58.0 %	51.0 %
Tar acids	trace	0.0 %
Distillation:		
Distillate to 170° C	0.60%	0.50%
Distillate 170° to 205° C	0.90%	0.50%
Distillate 205° to 235° C	6.90%	1.70%
Distillate 235° to 270° C	11.40%	9.90%
Distillate 270° to 315° C	7.90%	15.00%
Residue above 315° C	72.30%	72.40%
	100.00%	100.00%
Character of residue	hard	hard
Insoluble in dimethyl sulphate	0.0 %	0.0 %
Paraffin scale	0.0 %	0.0 %

As compared with the distillate creosoting oils it will be noted that those containing tar residues are much less volatile. Owing to the presence of tar residue they are better waterproofing agents but more likely to bleed and produce a sticky surface in warm weather. All of the creosoting oils produced from tars have been found to be sufficiently antiseptic to prevent decay. There has been considerable prejudice on the part of engineers in favor of distillate oils which produce a cleaner and more attractive block than do those containing tar residues. As the latter are considerably cheaper, however, and offer certain advantages from the standpoint of durability and protection of the block from expansion caused

by undue water absorption, their rapidly increasing use is apparently assured.

TESTING BITUMINOUS MATERIALS

32. Conditions Governing Testing

Standard Methods. The testing of bituminous materials for use in highway engineering dates back to the early days of the sheet-asphalt paving industry. The original tests applied were a few crude physical tests which, while reasonably satisfactory for those experienced in the use of the then limited number of available materials, were not based upon sound scientific principles. The gradual increase in the number of materials available for highway engineering, the widely varying characteristics of different types and grades of these materials, and the many methods of treatment and construction in common use have necessitated an improvement and expansion of the older tests. A number of physical and chemical tests are now in use and much work has been done by chemists and engineers towards the standardization of the methods involved. More complete standardization is needed, however, in order to correlate and properly interpret the results of tests obtained by different laboratories and investigators. The methods described in this chapter are mainly limited to those in general use. Methods of chemical analysis which are not ordinarily used in routine testing have not been included. Most of the tests given are physical rather than purely chemical and are commonly indicated in specifications for bituminous materials.

Representative Samples. In order that tests shall truly show the characteristics of a large bulk of material it is, of course, necessary that each test shall be made upon a representative sample. Methods of obtaining such samples under different conditions are treated under Art 53. It may sometimes happen, however, that a sample received at the laboratory lacks uniformity due to segregation of the constituents during shipment or storage of the sample. This is particularly true of the more fluid bituminous materials which contain a considerable amount of impurities. In any event, thoro mixing of the sample is advisable before taking a portion for examination. Mixing frequently involves heating the material, in which case special care should be exercised to prevent loss of the lighter constituents by volatilization and consequent changes in certain characteristics. The same care should be exercised when the sample contains water and it becomes necessary to remove the water or dry the sample before making a test. The proper method of drying will depend to a great extent upon the nature of the material under examination. Evaporation of the water by placing the sample in an oven, distillation, application of a partial vacuum, desiccation over sulphuric acid, or other hygroscopic medium, natural gravimetric separation, and centrifuging are the methods most commonly employed for drying samples. After receiving a representative sample, care must be taken that it does not suffer change during the necessary manipulation prior to making an actual test.

Normal Temperature. As bituminous materials are often appreciably affected by very slight variations in temperature, the exact temperature at which a test is to be made is often specified. Normal temperature as applied to laboratory tests is taken at 25° C (77° F), which is considered as about average room temperature. Certain physical tests are almost invariably made at exactly 25° C (77° F) and, whenever the exact temperature of a test is not specified, it is understood that the temperature at

which it is to be made should preferably be at or near normal temperature, altho absolute regulation may not be necessary. The results of chemical tests are not so markedly affected by slight temperature changes as are the physical tests.

33. Specific Gravity

Basis of Determination. The specific gravity of most bituminous materials used in highway engineering is based upon the relative weights of equal volumes of the bituminous material and water at normal temperature and is usually expressed as Specific Gravity 25°/25° C (77°/77° F). As the weight of a given volume of almost every material varies at different temperatures, the temperature basis of comparison should always be indicated for very accurate work. A few bituminous materials, such as certain tar distillates, separate solid material, mostly naphthalene at 25° C (77° F), and as this makes it difficult to determine the specific gravity at that temperature, the determination is made at a temperature sufficiently high to insure complete fluidity. When this is done water at the same temperature or at 25° C (77° F) may be taken as unity. In either case the basis of comparison should be indicated. Thus, if the weight of a given volume of the material is obtained at X° C and compared with water at 25° C (77° F), the basis of comparison should be expressed as follows: Specific Gravity X° C / 25° C. An older temperature basis of comparison, which is still used to a considerable extent by manufacturers and also by the United States Government in the calibration of the volume of tank cars and other containers, is 15.5° C (60° F). If the coefficient of expansion of the material is known and the specific gravity basis of comparison is given, it is very easy to translate any given determination to terms of another basis of comparison (see Art. 34). Such a method is commonly employed by manufacturers who, for the sake of simplicity and rapidity, prefer to make use of a hydrometer in the case of many materials which have to be first rendered more fluid by the application of heat. In reporting the specific gravity of fluid bituminous materials it is not uncommon to express results to four places to the right of the decimal point. Three decimal places are usually reported in the case of semisolid and solid materials, owing to the fact that the limit of accuracy is exceeded beyond this point.

Hydrometer Method. Where a sufficient quantity of material is available the specific gravity of thin fluid bituminous materials may be conveniently determined by means of a hydrometer. The Baumé scale for liquids lighter than water is commonly used by petroleum refiners and many oil products are sold upon a Baumé degree basis. A double scale hydrometer graduated for both direct specific gravity and degrees Baumé is therefore most convenient. Such hydrometers may be obtained in sets, each individual instrument being scaled for direct gravity between the limits of one or two units in the first place to the right of the decimal. When double scale hydrometers are not available, the results obtained by one scale may be transposed to the other by one of the following formulas:

LIQUIDS LIGHTER THAN WATER: $\text{SP. GR.} = \dfrac{140}{130 + {}^\circ\text{B}}$ or $^\circ\text{B} = \dfrac{140}{\text{SP. GR.}} - 130$

LIQUIDS HEAVIER THAN WATER: $\text{SP. GR.} = \dfrac{145}{145 - {}^\circ\text{B}}$ or $^\circ\text{B} = 145 - \dfrac{145}{\text{SP. GR.}}$

It will be seen from these formulas that the same degree Baumé for the two scales does not indicate the same specific gravity. Thus in the scale

for liquids lighter than water, 10° B equal 1.000 specific gravity, while in the scale for liquids heavier than water 0° B equals 1.000 specific gravity and 10° B equal 1.0741 specific gravity. Most hydrometers are based upon the specific gravity at 15.5°/15.5° C. If the material tested is at 25° C it is evident that, without taking into account the coefficient of expansion of the hydrometer itself, the actual basis of comparison is then 25°/15.5° C. For all practical purposes this may be converted to the 25°/25° C basis by multiplying the reading obtained by the factor 1.002 which corrects for the decrease in weight of a unit volume of water raised from 15.5° to 25° C. Thus: Sp. Gr. 25°/25° C = Sp. Gr. 25°/15.5° C × 1.002. If the specific gravity is obtained at a considerably elevated temperature the coefficient of expansion of the hydrometer itself should be properly taken into account as well as that of water and the material examined. As the average hydrometer measures from 10 to 14 in in length, a cylindrical glass vessel or hydrometer jar about 14 in high and 2 in diameter makes a convenient receptacle for the material examined. When making the determination the material should first be brought to the desired temperature and the proper hydrometer then inserted. In case the hydrometer sinks slowly, owing to the viscosity of the material, it should be given sufficient time to come to a definite resting point, and this point should be checked by raising the hydrometer and allowing it to sink a second time. The hydrometer should never be pushed below the point at which it naturally comes to rest until the last reading has been made where the miniscus of the liquid cuts the scale. It may then be pushed below the reading for a distance of three or four of the small divisions of the scale, whereupon it should immediately begin to rise. If it fails to do so, the material is too viscous for the hydrometer method, and another method should be employed. Tables XXVII and XXVIII give the specific gravity equivalents of Baumé degrees for liquids lighter than water and liquids heavier than water.

Table XXVIII.—*Continued*

A Westphal Balance (see Fig. 21) is convenient for quickly determining the specific gravity of comparatively small quantities of fluid bituminous materials, particularly fluid distillates. By using a vertical cylindrical container about ⅝ in diameter, it may be possible to use this instrument with as little as 15 cu cm of material. The determination is made by balancing a plummet in the liquid, the scale of the balance and the weights used being so designed as to give direct specific gravity readings. The Westphal balance is usually calibrated for 15.5°/15.5° C determinations and the results obtained are subject to the same corrections as noted under the HYDROMETER METHOD.

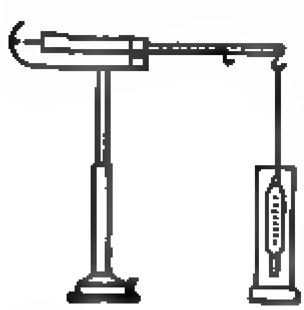

Fig. 21. Westphal Balance

Sprengle Tube. For determining the specific gravity of very small quantities of fluid materials the Sprengle or Nicholls tube, which is really a very small specially shaped pycnometer, is well

adapted. These instruments may be made with a capacity as low as 0.5 cu cm. The tube may be shaped as shown in Fig. 22, and may be conveniently suspended by a wire above the pan of an analytical balance. One arm of the tube is drawn out to a fine capillary opening. The other arm is somewhat larger but open and carries a mark to which the instrument is filled by sucking in the material thru the smaller arm. Any excess beyond the mark may be removed by means of a small piece of blotting paper. The instrument is first weighed empty, then filled to the mark with water at 25° C (77° F) and again weighed. It is then emptied, thoroly dried and filled to the mark with the material under examination. The weight of material divided by the weight of water gives the specific gravity.

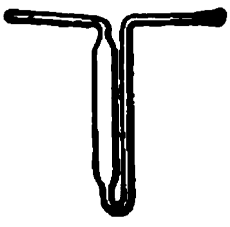

Fig. 22. Specific Gravity Tube

Pycnometer Methods. A pycnometer may be satisfactorily used for determining the specific gravity of both fluid and semisolid bituminous materials. One of special design such as shown in Fig. 23 is most convenient for general use as the ordinary narrow neck pycnometer is not well adapted for the viscous fluid and semisolid products. This instrument and its method of use, substantially as described by Hubbard and Reeve (25b) and recommended by the Spec. Com. Mat. Road Cons., Am. Soc. C. E. (13), is as follows: The pycnometer consists of a fairly heavy straight-walled glass tube, 70 mm long and 22 mm in diameter, ground to receive a solid glass stopper with a hole 1.6-mm bore in place of the usual capillary opening. The lower part of this stopper is made concave in order to allow all air bubbles to escape thru the bore. The depth of the cup-shaped depression is 4.8 mm at the center. The stoppered tube has a capacity of about 24 cu cm and when empty weighs about 28 g. Its principal advantages are (1) that any desired amount of bituminous materials may be poured in without touching the sides above the level desired; (2) it is easily cleaned; (3) on account of the 1.6-mm bore, the stopper can be more easily inserted when the tube is filled with a very viscous oil than if it contained a capillary opening. When working with semisolid bituminous materials which are too soft to be broken and handled in fragments, the following method of determining their specific gravity has been employed with good results. The clean, dry pycnometer is first weighed empty and this weight is called *a*. It is then filled in the usual manner with freshly distilled water at 25° C (77° F), and the weight is again taken and called *b*. A small amount of the bituminous material should be placed in a spoon and brought to a fluid condition by the gentle application of heat, with care that no loss by evaporation occurs. When sufficiently fluid, enough is poured into the dry pycnometer, which may also be warmed, to fill it about half full, without allowing the material to touch the sides of the tube above the desired level. When testing semisolid or solid materials, care should be taken in filling the pycnometer to avoid entrapping air. The tube and contents are then allowed to cool to room temperature, after which the tube is carefully weighed with the stopper. This weight is called *c*. Distilled water at 25° C (77° F) is then poured in until the pycnometer is full. After this the stopper is inserted, and the whole cooled to 25° C (77° F) by a 30-min immersion in a beaker of distilled water maintained at this temperature. All surplus moisture is then removed with a soft cloth, and the pycnometer and contents are weighed. This weight is called *d*. From the weights obtained

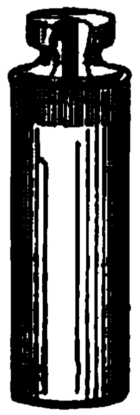

Fig. 23. Hubbard Pycnometer

the specific gravity of the bituminous material may be readily calculated by the following formula:

$$\text{SPECIFIC GRAVITY, } 25°/25° \text{ C } (77°/77° \text{ F}) = \frac{c - a}{(b - a) - (d - c)}$$

Both a and b are constants and need be determined but once. It is, therefore, necessary to make only two weighings for all determinations after the first. Results obtained according to the method given above are accurate to within 2 units in the third decimal place, while the open-tube method commonly employed is accurate to the second decimal place only. The specific gravity of fluid bituminous material may be determined in the ordinary manner with this pycnometer by completely filling it with the material and dividing the weight of the bituminous material thus obtained by that of the same volume of water.

Displacement Method. The specific gravity of bituminous materials which are sufficiently solid to handle in fragments at 25° C (77° F) may be determined by weighing a representative fragment in air and then in water at 25° C (77° F) If the determination is made upon an analytical balance, it is convenient to suspend a small fragment by means of a waxed silk thread from the hook on one of the pan supports, about 1½ in above the pan. Its weight is taken and called a. It is then weighed immersed in a beaker of water as shown in Fig. 24 and this weight called b. The specific gravity may then be calculated by means of the following formula:

$$\text{SPECIFIC GRAVITY} = \frac{a}{a - b}$$

This method is satisfactory for the determination of the specific gravity of compressed bituminous aggregates such as asphalt block and sections of sheet-asphalt or bituminous concrete pavement. In the case of coarse aggregates a much larger balance than the ordinary analytical balance may be required to weigh a representative sample.

Fig. 24. Displacement Method for Specific Gravity

Value of Specific Gravity Determinations. The specific gravity determination is commonly made upon all types and grades of bituminous materials with the exception of loose or uncompressed bituminous aggregates. It is one of the most valuable means of identifying a bituminous material and when considered in connection with other tests is often of service in determining the suitability of the material for a given use. In specifications it is used for both purposes and also for the sake of controlling uniformity of supply from a given source. In the examination of bituminous aggregates or sections of bituminous pavement it is of very material use in determining the degree of compression or percentage of voids which are present (see Art. 35), also the volume relations of bitumen and aggregates (see Art. 44). In general, bituminous materials tend to classify themselves according to specific gravity as shown by the following diagram which gives the approximate or average specific gravity limits of the more important types and grades. The pure bitumen of petroleum and asphalt products

in common use in highway engineering seldom exceeds 1.055 and of tars 1.18. A higher specific gravity therefore usually indicates the presence of mineral matter or heavy inorganic impurities. As many bituminous materials are purchased and used upon both a weight and a volume basis, the specific gravity determination is of use as a means of comparison. In this connection Fig. 26 shows the number of pounds per gallon and gallons per ton of materials having a specific gravity lying between 0.8 and 1.3. The further significance of the specific gravity determination will be considered in connection with other tests described in the following pages.

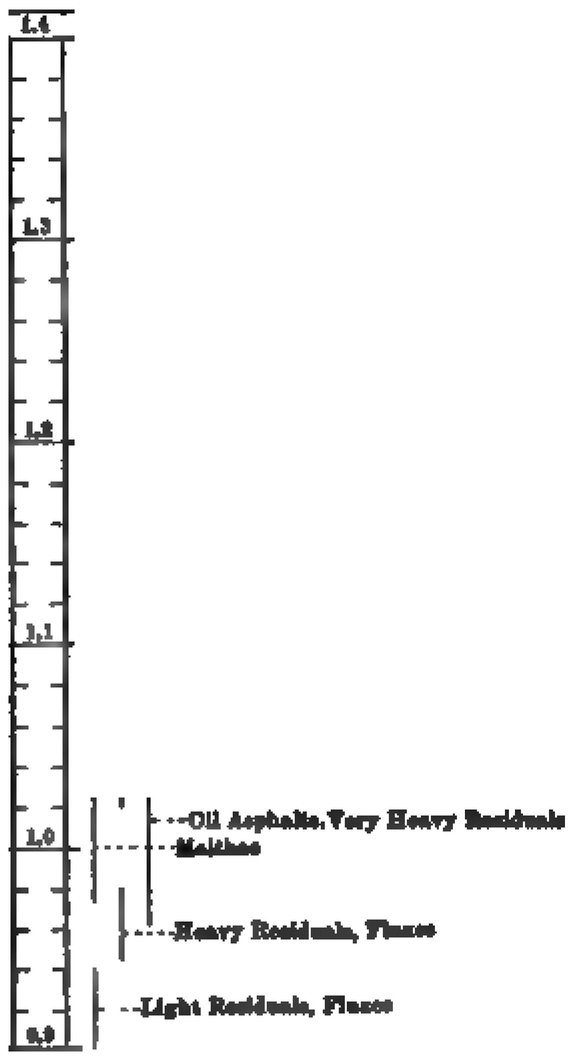

Fig. 26. Specific Gravity of Bituminous Materials

34. Coefficient of Expansion

Basis of Determination. The coefficient of volume or cubical expansion of any substance is the ratio between the increase in volume which it undergoes when its temperature is raised one degree and its original volume. The original or unit volume is set at some standard temperature. In the case of bituminous materials normal temperature, 25° C (77° F), is con-

venient to use, altho for the same reason that the specific gravity determination may be required at 15.5° C (60° F) this temperature is also sometimes taken as standard. The coefficient of expansion may be expressed either in terms of the Centigrade or Fahrenheit scale. If K represents the coefficient of expansion, then $K°\ C = 9K°\ F/5$ and $K°\ F = 5K°\ C/9$. The coefficient of expansion of most materials varies slightly at different temperatures and for this reason the volume change which is undergone between comparatively wide ranges of temperature is divided by the number of degrees of temperature and the average coefficient of expansion calculated. It is the average coefficient of expansion of bituminous materials which is of most interest from a practical standpoint. As a material ex-

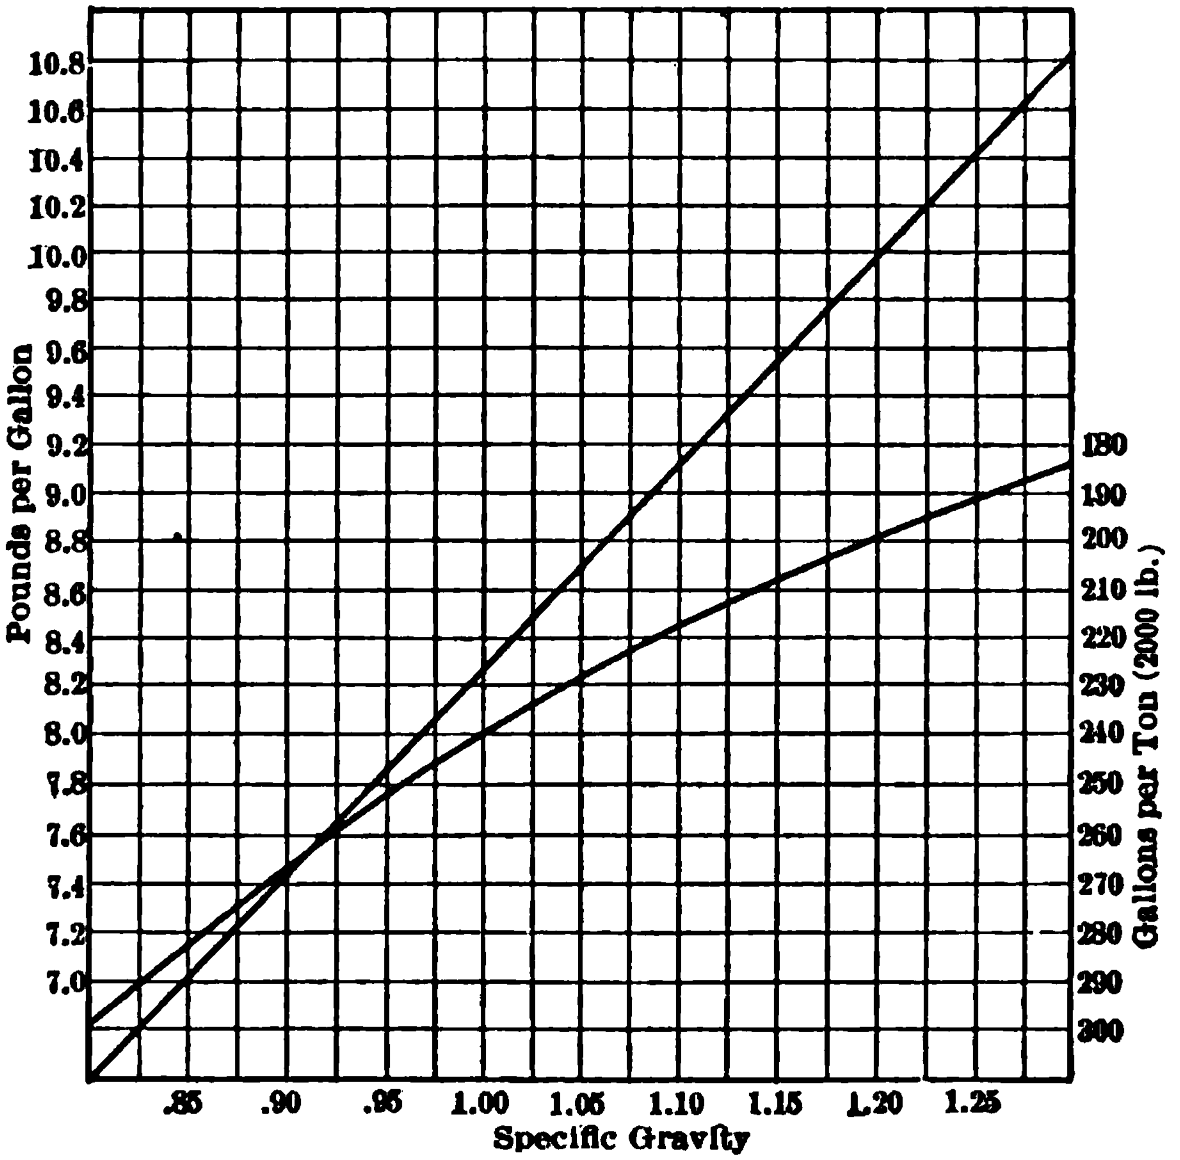

Fig. 26. Weight and Volume Relations

pands under the action of heat its specific gravity becomes less. It is thus possible to calculate K from volume measurements at different temperatures or from specific gravity determinations at different temperatures.

Volume Method. In the volume method of determining the coefficient of expansion, the bituminous material, in a fluid state, is poured into a glass receptacle known as a dilatometer, which consists of a large bulb with a long graduated narrow neck. This instrument is calibrated at normal temperature so that when filled to any mark on the graduated neck its contents are known. The determination is made by first bringing the dilatometer and contents to normal temperature and reading the position of the miniscus on the graduated neck. The instrument is then placed in

a carefully regulated oven and heated to any desired temperature. When its temperature is uniform the position of the miniscus is again read. The apparent volume at the elevated temperature is not the actual volume owing to the expansion which the instrument itself has undergone in acquiring the observed temperature. A correction has therefore to be made for the expansion of the glass, the cubical coefficient of expansion of which has been previously ascertained. The coefficient of expansion of the material is then determined by means of the following formula, where V represents the volume at normal temperature, V' the actual volume at the observed temperature, t normal temperature, and t' the observed temperature: $K = \frac{V' - V}{V\,(t' - t)}$. The volume method, while satisfactory for fluids, is not well adapted for use in connection with semisolid and solid bituminous materials and the specific gravity method is therefore to be preferred.

Specific Gravity Method. In the case of very viscous liquids, semisolids and solids, the pycnometer method as described in Art. 33 is first used to determine the specific gravity of the material at normal temperature. The weight of the water contents of the pycnometer at any desired elevated temperature is then obtained and another specific gravity determination made of the material at this elevated temperature as compared with water at the same temperature. From the known K of water, which is about 0.0002 per ° C, the specific gravity of the material at the elevated temperature is then determined as compared with water at normal temperature. The coefficient of expansion of the material is then determined by means of the following formula when G represents the specific gravity at normal temperature and G' represents the specific gravity on the same basis at the observed temperature: $K = \frac{G - G'}{G'\,(t' - t)}$.

Value of Coefficient of Expansion Determination. The practical value of the coefficient of expansion determination lies in its application to volume changes which take place upon heating bituminous materials, especially when the material is purchased or used upon a volume basis, which is often the case. In the vicinity of refineries, bituminous materials for hot surface application or bituminous macadam construction are not uncommonly delivered at the site of the work in tank wagons or tank cars at a temperature ready to apply. As the purchase price and rate of application are ordinarily based upon volumes at 15.5° C (60° F), it is necessary to know the coefficient of expansion of the material in order to compute the volume at such temperature. In some cases an arbitrary figure is mutually agreed upon. Thus for residual petroleums the coefficient of expansion is often assumed as 0.00072 per ° C (0.0004 per ° F), and in measuring hot oils a deduction of 0.72% is made for every 10° C above 15.5° C (0.4% for every 10° F above 60° F) which is commonly taken as standard temperature. The general formulas for finding volumes when K is known are as follows:

$$V = \frac{V'}{K\,(t' - t) + 1} \qquad V' = V\,[K\,(t' - t) + 1]$$

Based upon the arbitrary standard for oils above mentioned, Fig. 30 illustrates a convenient graphic method of showing (1) the number of gallons

at elevated temperatures represented by 100 gal at 15.5° C (60° F); and (2) the number of gallons at 15.5° C (60° F) represented by 100 gal at various elevated temperatures when the coefficient of expansion is 0.00072 per ° C (0.0004 per ° F). Comparatively little data is to be had relative to the coefficient of expansion of the various bituminous road and paving materials. In general, however, for a given type of material the coefficient of expansion decreases as the specific gravity increases. Thus the K of a crude petroleum or tar is greater than that of its residues and less than that of its distillates. From the data that is available it appears that the values of K, in Table XXIX, are reasonable averages for the types of materials listed. These figures are, however, only approximate and in certain cases are subject to considerable variation.

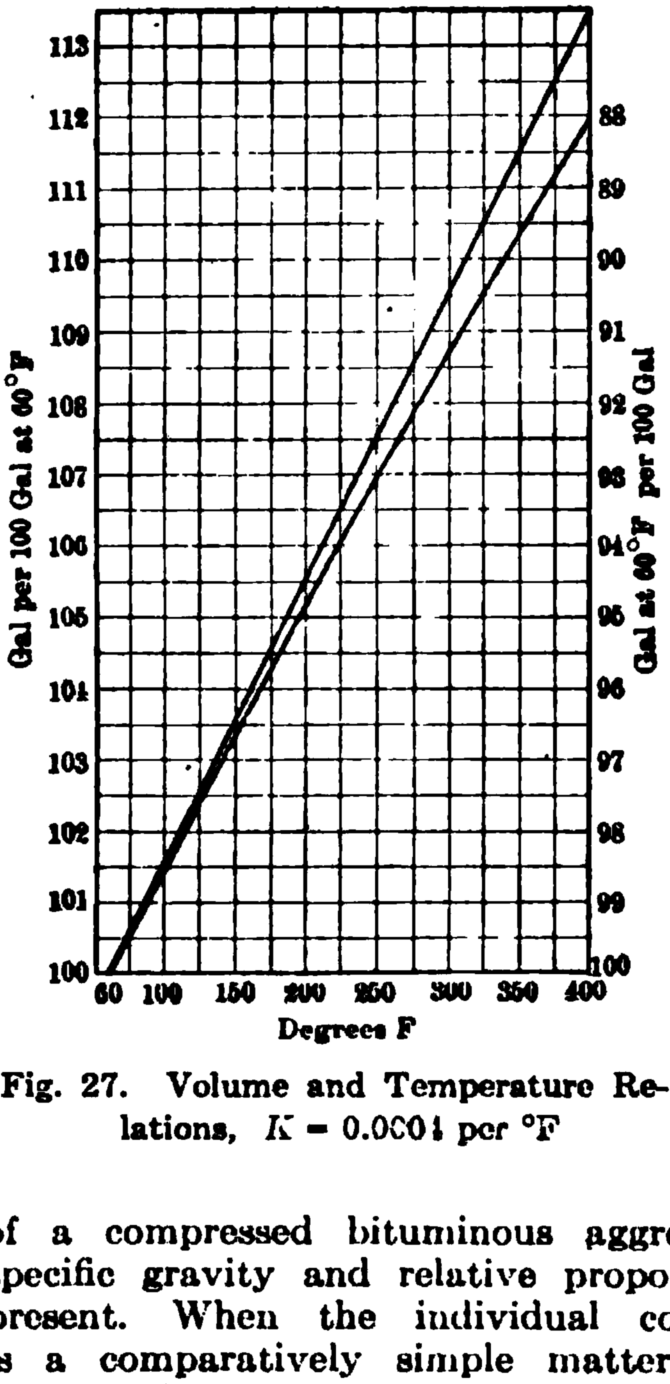

Fig. 27. Volume and Temperature Relations, $K = 0.0004$ per °F

35. The Density and Voids in Bituminous Aggregates

Theoretical Maximum Density of Compressed Bituminous Aggregates. Without reference to grading or practical possible compression, the theoretical maximum density of a compressed bituminous aggregate may be calculated from the specific gravity and relative proportions of the individual constituents present. When the individual constituents are at first hand this is a comparatively simple matter, but when a mixed aggregate or section of compressed pavement is under examination it is first necessary to remove and recover the bitumen, the percentage of which must also be determined (see Art. 44). The specific gravity of the recovered bitumen may then be determined by the pycnometer method as described in Art. 33 and that of the mineral aggregate by any of the well-known

Table XXIX.—Approximate Coefficients of Expansion of Bituminous Materials

Material	K per ° C	K per ° F
Gasoline	0.00090	0.00050
Creosoting oils	0.00080	0.00044
Fluid residual petroleums	0.00070	0.00039
Fluid tars	0.00060	0.00033
Asphalt cements	0.00055	0.00030
Heavy refined tars	0.00055	0.00030

methods for mineral particles. If coarse particles are present it is advisable to screen the aggregate into two or more sizes and determine the specific gravity of each. Thus a mixture of crushed rock and sand may be passed over a ¼-in screen. If all material retained on the screen then appears to be the same kind of stone the specific gravity of a single fragment is taken as representing the entire portion. The specific gravity of the entire finer portion may be determined by means of a Chatelier or Jackson apparatus, such as used in cement examination, or other similar method. After the gravity and percent by weight of the various constituents have been determined, their volume proportions are calculated by dividing their weight percentages by their respective specific gravities. The ratio of the sum of the weight proportions to the sum of the volume proportions is then the theoretical maximum density of the mix. When the percent by weight and specific gravity of two or three constituents are given, the following formula may be used if D represents the maximum possible density, W, W' and W^2 represent the percent by weight, and G, G' and G^2, their respective specific gravities.

TWO CONSTITUENTS

$$D = \frac{100}{W/G + W'/G'}$$

THREE CONSTITUENTS

$$D = \frac{100}{W/G + W'/G' + W^2/G^2}$$

The Probable Maximum Density of Compressed Bituminous Aggregates may be determined experimentally in the laboratory by heating the mixed aggregate to proper working temperature and compressing it in a cylindrical mold fitted with a plunger, which has also been heated to the same temperature. The plunger may be forced into the mold by means of a compression machine or heavy hammer. Upon cooling, the specimen is forced from the mold and its specific gravity determined by the ordinary displacement method. The probable maximum density is largely dependent upon the grading of the mineral particles, which is a most important consideration for fine aggregates. For a well graded fine aggregate carrying the proper percentage of bituminous cement, the probable maximum density should closely approach the theoretical maximum density.

The Actual Density of Compressed Bituminous Aggregates, such as a section of a bituminous concrete pavement, is directly determined by means of the displacement method (see Art. 33). If satisfactory compression has been obtained in the construction of the pavement its density should closely approach the probable maximum density as obtained by a laboratory test upon a section of the pavement which is first softened and disintegrated by warming and then compressed at proper working temperature, as described in the preceding paragraph.

Voids in Compressed Bituminous Aggregates. The percent of voids in a compressed bituminous aggregate is determined from the actual density of the compressed aggregate as compared with the theoretical maximum density which allows for no voids. Thus if D represents the theoretical maximum density and d the actual density, the percent of voids is determined by the following formula:

$$\text{PERCENT OF VOIDS} = \frac{100\,(D - d)}{D}$$

If proper compression has been secured in the construction of a bituminous concrete pavement, the percentage of voids as above determined should closely correspond with the voids in a properly prepared laboratory com-

pressed sample. If a fine aggregate is well graded and carries the proper percentage of bituminous cement, the voids should be very low and seldom over 3 or 4%.

36. Viscosity

Viscosimetry is the measurement of resistance to flow. In the natural movement of all liquids seeking a lower level or a level of less external pressure, internal friction is developed which tends to retard the flow. External friction is also developed between the liquid and the surrounding surface or substance. Both internal and external friction are therefore factors to be considered in the measurement of viscosity. The more common types of viscosimeters are based upon the principle of measuring the time of flow of a given quantity of liquid under a given head thru a given orifice. In such instruments it is evident that the relative retardation of flow caused by internal and external friction is largely dependent upon the size, shape and character of the orifice. For this reason the viscosity value obtained is more or less arbitrary. Liquid bituminous materials vary greatly in viscosity among themselves and the viscosity of a given material is greatly affected by the temperature of the material. In reporting the results of a viscosity test it is therefore important that all conditions of the test should be indicated or understood. The pressure or head, temperature and volume of liquid measured as passing the orifice are factors which may be controlled by the operator. As the orifices of different instruments of the same make are subject to unavoidable slight variations which affect the results of a test, it is customary to consider the viscosity of water for any given instrument as unity and to express the results of testing other liquids in terms of water as so-called specific viscosity. This tends to correct and place upon the same basis different instruments of the same make but it does not make the actual results obtained by different types of viscosimeters by any means the same. In expressing specific viscosities, it is therefore necessary to state the make or type of viscosimeter, of which there are several. While many of these instruments are admirably adapted for use in connection with certain liquids, none has yet been devised which really meets the requirements for successfully testing the wide range of liquid bituminous materials used in highway engineering. Of those which are available for this purpose, the Engler viscosimeter is, however, most generally used.

The Engler Viscosimeter, which is shown in Fig. 28, consists of a brass vessel *a*, with a cover *b*, for holding the material to be tested. To the conical bottom of *a* is fitted a conical outflow tube *c*, exactly 20 mm long, with a diameter on top of 2.9 mm and on the bottom of 2.8 mm. This tube can be closed and opened by the pointed hardwood stopper *d*. Pointed metal projections are placed on the inside of *a* at equal distances from the bottom and serve for measuring the charge of material, which is 240 cu cm. The thermometer *e* is used to ascertain the temperature of the material to be tested. The vessel *a* is surrounded by a brass jacket *f*, which holds the material used as a heating bath, either water or cottonseed oil, according to the temperature at which the test is to be made. A tripod *g* serves as a support for the apparatus and also carries a ring burner *h* by means of which the bath is directly heated. A measuring cylinder of 100 cu cm capacity, which is sufficiently accurate for work with road materials, is placed directly under the outlet tube. As all viscosity determinations should be compared with that of water at 25° C (77° F), the apparatus should

be previously calibrated as follows: The cup and outlet tube should first be scrupulously cleaned. A piece of soft tissue paper is convenient for cleaning the latter. The stopper is then inserted in the tube and the cup filled with water at 25° C (77° F) to the top of the projections. The measuring cylinder should be placed directly under the outflow tube so that the material, upon flowing out, will not touch the sides, and the stopper may then be removed. The time required both for 50 and 100 cu cm to run out should be ascertained by means of a stop-watch and the results so obtained should be checked a number of times. The time required for 50 cu cm of water should be about 11 sec, and for 100 cu cm about 22.8 sec. The use of the Engler viscosimeter in determining the viscosity of liquid bituminous materials at any desired temperature was recommended by the Spec. Com. Mat. Road Cons., Am. Soc. C. E. (13) as follows: "Bituminous materials shall be tested in the same manner as water, and the temperature at which the test is made shall be controlled by the bath. The material shall be brought to the desired temperature and maintained there for at least 3 min before making the test. The results are expressed as specific viscosity compared with water at 25° C (77° F), as follows:

Fig. 28. Engler Viscosimeter

$$\text{SPECIFIC VISCOSITY AT —° C (—° F) FOR — CUBIC CENTIMETERS} = \frac{\text{SECONDS FOR PASSAGE OF GIVEN VOLUME AT —° C (—° F)}}{\text{SECONDS FOR PASSAGE OF SAME VOLUME OF WATER AT 25° C (77° F)}}.$$

For very thin fluid bituminous materials the specific viscosity is usually determined at 25° C (77° F) with 100 cu cm. The more viscous fluid products are usually run at 40° or 50° C (104° or 122° F) with 50 cu cm and very viscous products at 100° C (212° F) or over with 50 cu cm.

Value of Viscosity Determination. Unfortunately the Engler viscosimeter is not well adapted for determining the specific viscosity of many bituminous materials at 25° C (77° F). As, for the different types of materials, viscosity at a higher temperature is no definite measure of their viscosity at 25° C (77° F), it is evident that a satisfactory comparison of their specific viscosities at normal temperature cannot be obtained by this means. As a means of such comparison the use of the instrument at higher temperatures is limited to materials of the same type. The interpretation of the test except with reference to identification and control of a given type and grade of material is therefore somewhat complicated. If, however, it is desired to apply a bituminous material at a given temperature, as for instance when it is to be heated in a tank car by means of steam, a determination of its viscosity at that temperature is often of value. It is impossible to state in a general way just what the viscosity of a material for surface application should be during application, as this is largely dependent upon the

type of distributor, its spraying nozzles and its speed control. It is a fact, however, that many materials sold for cold surface application are entirely too viscous at normal temperature for uniform distribution at the proper rate of distribution, but what may be a too high viscosity for one type of material may not be too high for another type. As a measure of consistency at normal temperature, it would appear advisable to limit the use of the Engler viscosimeter to those materials intended for cold application and when possible to utilize some other consistency test for indicating the consistency at normal temperature of those materials which have to be heated before application. In general, at normal temperature fluid distillates show a much lower specific viscosity than do fluid petroleums or tar residuums. Crude and dehydrated petroleums and tars vary greatly in viscosity. Among the petroleums, however, those of the asphaltic type are usually much more viscous than the paraffin or semiasphaltic type. Among the tars the viscosity of crude water-gas tar is lowest and gas-house coal tars from horizontal retorts the highest. Vertical and inclined retort tars usually hold an intermediate position in this respect together with coke-oven tars. For a given type of fluid residual petroleum or tar produced by fractional distillation, the specific viscosity increases with the specific gravity and decreases with the coefficient of expansion. As regards fluid residuums which are subjected to the blowing process, however, the viscosity may be greatly increased without markedly increasing the specific gravity of the residuum. The viscosity of all bituminous materials decreases as their temperature increases. In any bituminous material the presence of finely divided non-bituminous impurities held in suspension will often greatly increase the viscosity of the material, altho the actual viscosity of its pure bitumen may be low.

37. Float Test

The New York Testing Laboratory Float Test is used as a consistency test for very viscous fluid and soft semisolid bituminous materials. The float test is recommended for use by the Spec. Com. Mat. Road Cons., Am. Soc. C. E. (13). As shown in Fig. 29, the apparatus consists of two parts, an aluminum float or saucer *a* and a conical brass collar *b*. The two parts are made separately, so that one float may be used with a number of brass collars. In making the test the brass collars should be placed with the small end down upon a brass plate which has been previously amalgamated with mercury by rubbing it first with a dilute solution of mercuric chloride or nitrate and then with mercury. A small quantity of the material to be tested is heated in a metal spoon until quite fluid, care being taken that it suffers no appreciable loss by volatilization and that it is kept free from air bubbles. It is then poured into the collar in a thin stream until slightly more than level with the top. The surplus may be removed, after the material has cooled to room temperature, by means of a spatula blade which has been slightly heated. The collar and plate are then placed in ice water maintained at 5° C (41° F), and left in this bath for at least 15 min. Meanwhile a cup or pan of sufficient depth is filled about three-fourths full of water and placed on a tripod, and the water is heated to any desired temperature at which the test is to be made. This temperature should be accurately maintained and should at no time during the entire test be allowed to vary more than 0.5° C (0.9° F) from the temperature selected. After the material to be

tested has been kept in the ice water for at least 15 min, the collar and contents are removed from the plate and screwed into the aluminum float, which is then immediately floated in the warmed bath. As the plug of bituminous material becomes warm and fluid, it is gradually forced upward and out of the collar until water gains entrance to the saucer and causes it to sink. The time in seconds between placing the apparatus on the water and when the water breaks thru the bituminous material is determined by means of a stop-watch and is taken as a measure of the consistency of the material under examination. The test is preferably made at 50° C (122° F). Very soft products which show a test at this temperature of only a few seconds, however, may be advantageously tested at a lower temperature, such as 32° C (90° F). If the test at 50° C (122° F) requires over 4 or 5 min, it is sometimes made at 65° C (149° F), and, if the melting point of the material is high, the test is run at 100° C (212° F). In any case it is evident that the test temperature must be higher than the melting point of the material tested.

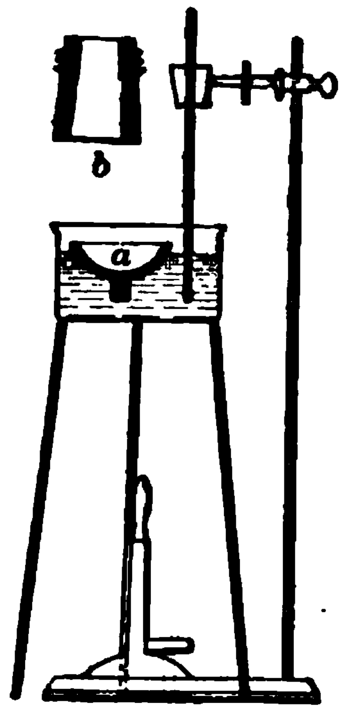

Fig. 29. N. Y. Testing Laboratory Float Apparatus

Value of the Float Test. The float test has sometimes been called a viscosity test. In some respects it is a measure of the resistance to flow possessed by the material, but it differs from the average viscosity test mainly in the fact that the temperature of the material itself is constantly changing during the test. It cannot be used with very fluid materials, but for the very viscous fluids which become almost semisolid at the temperature of ice water and for many normally semisolid products it serves as a satisfactory measure of consistency at normal temperature, altho the test itself is conducted at a higher temperature. Providing the temperature of the test is the same, it serves reasonably well as a basis of comparing the consistency at normal temperature of both straight residual and fluxed products of the same type. It has the distinct advantage over the viscosity test of being less susceptible to the influence of inert, finely divided suspended material which may be present, because of the comparatively large orifice of the collar. For this reason it more nearly represents the consistency of the actual bitumen, and is particularly well adapted for determining the consistency of tars irrespective of their free carbon content. In this connection it is used to a considerable extent as a control test in the manufacture of heavy residual tars. It is not so well adapted for testing the semisolid blown oil products which conduct heat so slowly that only the surface in contact with the collar becomes fluid before the entire plug of semisolid material is forced out. For a given type of residual material the float test at a given temperature decreases with the specific gravity. For any material it naturally decreases as the temperature of the test is increased. For fluid products which harden rapidly upon exposure, such as cut-backs, the float test is useful as a means of determining the consistency of the residue from the volatilization test (see Art. 42), especially the soft residues which cannot well be subjected to the penetration test. Most residual tars suitable for use as carpeting mediums show a float test at 50° C (122° F) of between 40 and 120 sec, while the more solid tar residues used as bituminous cements for

construction work show a float test at this temperature of from 120 to 200 sec.

38. The Penetration Test

Penetration Machines. The penetration test is one of the oldest and most widely used tests for determining the consistency of semisolid and solid petroleum and asphalt products. There are a number of penetration machines in common use which employ the same standards of test and therefore give practically equivalent results. Among them may be mentioned the Dow, the New York Testing Laboratory, and the Humboldt penetrometers. The Dow machine, shown in Fig. 30, is probably used more than any other. This apparatus consists of a standard needle *a* inserted in a short brass rod, which is held in an aluminum rod *b* by a binding screw. The aluminum rod is secured in a framework so weighted and balanced that, when it is supported on the point of the needle, the framework and rod will stand in an upright position, allowing the needle to penetrate perpendicularly without the aid of a support. The frame, aluminum rod and needle weigh 100 g with the weight *c* on the bottom of the frame, while without the weight they weigh 50 g. Fig. 30 shows the needle and weighted frame, together with side and front views of the entire apparatus, put together and ready for making a penetration. The shelf for the sample is marked *d*; *e* is the clamp to hold the aluminum rod until it is desired to make a test; and *f* is a button which, when pressed, opens the clamp. By turning this button while the clamp is being held open it will lock and keep the clamp from closing until unlocked. The device for measuring the distance penetrated by the needle consists of a rack with a foot *g*. The movement of this rack turns a pinion, to which is attached the hand which indicates on the dial *h* the vertical distance covered by the rack. One division of the dial corresponds to a movement of 0.1 mm by the rack. The rack may be raised or lowered by moving the counterweight *i* up or down. The tin box containing the sample to be tested is marked *k*; this is submerged in water contained in the glass cup in order to maintain a constant temperature. The penetration test is made as follows: A sample of the material to be tested is first warmed sufficiently to flow, and poured into the tin box. The box and contents, after cooling for 1 hr at room temperature, are immersed in water maintained at the temperature at which the test is to be made, and allowed to remain immersed for at least 1 hr. The sample in the tin box should then be placed in the glass cup and removed in it, covered with as much water as convenient without spilling, to the shelf *d*. The brass rod with the needle is inserted into *b* and secured by tightening the binding screw. The rod is lowered until the

Fig. 30. Dow Penetration Machine

point of the needle almost touches the surface of the sample; then, by grasping the frame with both hands, it is cautiously pulled down until the needle just comes in contact with the surface of the sample. This can be seen best by having a light so situated that, upon looking thru the sides of the glass cup, the needle will be reflected from the surface of the sample. After thus setting the needle, the counterweight is slowly raised until the foot of the rack rests on the head of the rod and a reading of the dial taken. The clamp is then opened wide by pressing the button and held in this position for exactly 5 sec, as determined by a pendulum or chronometer. The rack is then lowered until it rests on the rod, and the difference between the first and second readings of the dial in millimeters is taken as the distance penetrated by the needle. Owing to the susceptibility of certain bituminous materials to slight changes in temperature, the water bath should be accurately maintained at the desired temperature, both before and during the test, and, when the room temperature differs greatly from that of the bath, the water in the glass cup should be renewed after each test. An average of from three to five tests, which should not usually differ more than three units between maximum and minimum, is taken as the penetration of the sample. The needle should be removed and thoroly cleaned by wiping with a dry cloth, after which it is ready for another test. The point of the needle should be examined from time to time with a magnifying glass to see that it is not injured in any way. If it is found defective, it may be removed by heating the brass rod and withdrawing with pliers. A new needle may then be inserted in the heated brass rod, and held firmly in place by a drop of soft solder.

Am. Soc. Test. Mat. Method. In 1916, the Am. Soc. Test. Mat. adopted the following test for penetration of bituminous materials as standard:

"Definition of penetration. The consistency of a bituminous material, expressed as the distance that a standard needle vertically penetrates a sample of the material under known conditions of loading, time and temperature. Where the conditions of test are not specifically mentioned, the load, time and temperature are understood to be 100 g, 5 sec, 25° C (77° F) and the units of penetration to indicate hundredths of centimeters.

"Apparatus. The container for holding the material to be tested shall be a flat-bottomed, cylindrical dish, 55 mm (2 3/16 in) in diameter and 35 mm (1 3/8 in) deep.*

"The needle (35) for this test shall be a cylindrical steel rod 50.8 mm (2 in) long and having a diameter of 1.016 mm (0.04 in) and turned on one end to a sharp point having a 6.35-mm (1/4-in) taper. The water bath shall be maintained at a temperature not varying more than 0.1° C (0.18° F) from 25° C (77° F). The volume of water shall be not less than 10 liters and the sample shall be immersed to a depth of not less than 10 cm (4 in) and shall be supported on a perforated shelf not less than 5 cm (2 in) from the bottom of the bath. Any apparatus which will allow the needle to penetrate without appreciable friction, and which is accurately calibrated to yield results in accordance with the definition of penetration, will be acceptable. The transfer dish for container shall be a small dish or tray of such capacity as will insure complete immersion of the container during the test. It shall be provided with some means which will insure a firm bearing and prevent rocking of the container.

---

*This specification is fulfilled by the American Can Company's Gill style ointment box, deep pattern, 3-oz capacity.

"PREPARATION OF SAMPLE. The sample shall be completely melted at the lowest possible temperature and stirred thoroly until it is homogeneous and free from air bubbles. It shall then be poured into the sample container to a depth of not less than 15 mm (5/8 in). The sample shall be protected from dust and allowed to cool in an atmosphere not lower than 18° C (65° F) for 1 hr. It shall then be placed in the water bath along with the transfer dish and allowed to remain 1 hr.

"TESTING. In making the test the sample shall be placed in the transfer dish filled with water from the water bath of sufficient depth to completely cover the container. The transfer dish containing the sample shall then be placed upon the stand of the penetration machine. The needle, loaded with specified weight, shall be adjusted to make contact with the surface of the sample. This may be accomplished by making contact of the actual needle point with its image reflected by the surface of the sample from a properly placed source of light. Either the reading of the dial shall then be noted or the needle brought to zero. The needle is then released for the specified period of time, after which the penetration machine is adjusted to measure the distance penetrated. At least three tests shall be made at points on the surface of the sample not less than 1 cm (3/8 in) from the side of the container and not less than 1 cm (3/8 in) apart. After each test the sample and transfer dish shall be returned to the water bath and the needle shall be carefully wiped toward its point with a clean, dry cloth to remove all adhering bitumen. The reported penetration shall be the average of at least three tests whose values shall not differ more than four points between maximum and minimum. When desirable to vary the temperature, time and weight, and, in order to provide for a uniform method of reporting results when variations are made, the samples shall be melted and cooled in air as above directed. They shall then be immersed in water or brine, as the case may require, for 1 hr at the temperature desired. The following combinations are suggested: At 0° C (32° F) 200 g weight, 60 sec; at 46.1° C (115° F) 50 g weight, 5 sec."

Method Recommended to the Am. Soc. C. E. In 1918 the Spec. Com. Mat. Road Cons. (13) recommended the adoption of the 1916 Am. Soc. Test. Mat. standard method, except that the lowest temperature at which the penetration of the asphalt cement is taken should be 4° C (39° F) instead of 0° C (32° F).

Conditions Affecting the Penetration Test. From the above descriptions it is evident that many conditions affect the results of the penetration test. For those materials which show a high penetration the diameter of the container often exerts a marked influence upon the results obtained under a given set of conditions. As a result of experiments it has been determined that for such materials the diameter of the container should not be less than 1.25 in. It is most important that thruout the test the sample be maintained at exactly the given temperature as slight differences in temperature may markedly affect the results of test. Most materials appear to continue to harden somewhat upon standing after they have been cooled to normal temperature. Thus a sample prepared and tested within a period of 2 or 3 hr will often show, under the same conditions of test, a lower penetration the following day if it is not again melted and allowed to cool just prior to making the test.

Value of the Penetration Test. The penetration test is most commonly used in connection with asphalts and asphalt cements, altho it is sometimes used in testing the harder tar residuums. For the manufacture of the

former type of materials it serves as a control test. These materials are commonly graded by their penetration at 25° C (77° F), and in all cases where the term penetration is used without other qualification it is understood that the temperature of 25° C (77° F) is implied and that the test is made with a standard needle under a load of 100 g applied for 5 sec. The test is not so useful as a means of control or in grading the tar residuums used in highway engineering for the reason that most of these residuums are quite soft, and as their surface tension is very high they press out or deform under the loaded needle much more than do the asphalt cements commonly used. The true penetration is not therefore so accurately recorded, the result obtained representing to a very considerable extent the measure of surface deformation rather than actual penetration. In general, the more susceptible the bituminous material is to temperature changes, the greater its surface deformation under the loaded needle. Susceptibility to temperature changes may be determined by means of the penetration test made at the temperatures of 0° or 4°, 25°, and 46° C (32° or 39°, 77°, and 115° F), which serve as approximate minimum, average, and maximum temperatures of the pavement proper in which the material may be incorporated.

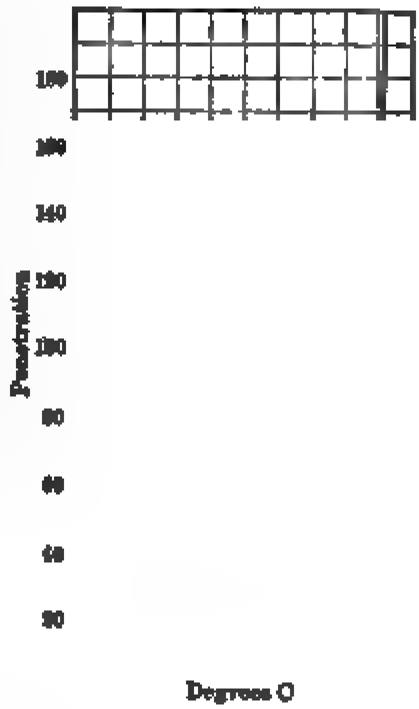

Fig. 31. Penetration of Straight Distilled and Blown Petroleums

Results of tests at 4° C (39° F) are more easily obtained than results at 0° C (32° F). Asphalt cements produced by the straight distillation of petroleums and those produced by fluxing the native asphalts with straight distilled residual fluxes are more susceptible to temperature changes than are those produced by the blowing process. This is illustrated by Fig. 31, which shows the penetration at the three temperatures of a straight distilled and a blown petroleum residuum or asphalt cement. It will be noted that while both materials show the same penetration at 25° C (77° F), the straight distilled product shows a lower penetration at 4° C (39° F) and a higher penetration at 46° C (115° F) than does the blown product. In this diagram the penetrations at 4° C (39° F) are made under a load of 200 g applied for 1 min and at 46° C (115° F) under a load of 50 g applied for 5 sec. The penetration of a given type of asphalt cement usually decreases as its specific gravity increases. In other words, it becomes harder. This relation, however, does not necessarily hold true in comparing different types. Thus an asphalt cement of given penetration produced by straight distillation of a California petroleum will usually show a much lower specific gravity than will one of the same penetration produced by the same method from a Mexican petroleum or by fluxing a native asphalt. Highly blown asphalt cements may usually be identified by a very low specific gravity as compared with residual and fluxed native asphalts of the same penetration. Thus, the penetration test, while practically valueless alone as a means of identification, owing to the fact that almost any type of material can be manufactured at any desired penetration, may be a valuable aid to

identification when considered in connection with the specific gravity of the material. No very definite general limits can be set for the proper penetration of asphalt cements for a given type of construction, as the limits vary not only with the type of material but also with the conditions which it will have to meet in service. In general, however, the penetration of asphalt cements used in the construction of sheet-asphalt or bituminous concrete pavements lies between the limits of 40 and 90, while those of higher penetration are generally used in bituminous macadam construction. Besides being applied to the original material, the penetration test is ordinarily made upon the residue obtained from the volatilization test of asphalt cements (see Art. 42) in order to determine the amount of hardening that has been produced. The penetration test is one of great importance in the plant inspection of asphalt cements prepared at the paving plant by fluxing refined asphalts. Especially where large quantities of asphalt cement are maintained for a long time at elevated temperatures, constant inspection is required, so that, as the product hardens, more flux may be added as required. In this connection a fluxing table or fluxing curve may be experimentally secured for a given refined asphalt and flux. A typical curve, showing the penetration at 25° C (77° F) of asphalt cements, produced by varying proportions of a refined asphalt and flux, is shown in Fig. 32. By means of such a curve it is a comparatively simple matter to determine at once how much flux to add to a known batch of material so as to raise the penetration from any given point to any higher point on the curve.

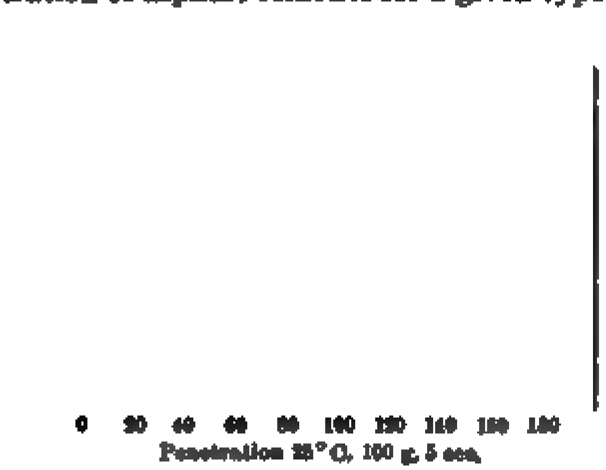

Fig. 32. Effect of Flux on Penetration of Asphalt

39. The Ductility Test

Ductility Machines of various design but operating on the same general principle have been used to a considerable extent in the testing of asphalt cements. The test was originated by Dow, whose machine is perhaps the best known. Other types in common use are the Kirschbraun machine and the Chew machine, which latter is shown in Fig. 33. In all of these machines a test specimen of the same standard size and shape is tested by pulling it apart at a given rate and noting the distance that it stretches before breaking. In some cases the pulling is accomplished by means of a gear operated by a hand wheel, but a motor drive, such as shown in the cut, is to be preferred, as it insures greater uniformity in the rate of pull. The Chew machine also has an automatic device for recording the rate of pull. The Spec. Com. Mat. Road Cons., Am. Soc. C. E. (13) recommended that the ductility test be conducted on bituminous materials as follows: "A briquet of the material to be tested shall be formed by pouring the molten material into a briquet mold. The dimension of the briquet shall be: 1 cm in thickness thruout its entire length; distance between the clips or end pieces, 3 cm; width of asphalt cement section at mouth of clips,

2 cm; width at maximum cross-section, half way between clips, 1 cm. The center pieces are removable, the briquet mold being held together during molding with a clamp or wire. The molding of the briquet shall be done as follows: the two center sections shall be well amalgamated to prevent the asphalt cement from adhering to them, and the briquet mold shall then be placed on a freshly amalgamated brass plate. The asphalt cement to be tested, while in a molten state, shall be poured into the mold, a slight excess being added to allow for shrinkage on cooling. When the asphalt cement in the mold is nearly cool, the briquet shall be cut off level, with a warm knife or spatula. When it is thoroly cooled to the temperature at which it is desired to make the test, the clamp and the two side pieces are removed, leaving the briquet of asphalt cement held at each end by the ends of the mold, which now play the part of clips. The briquet shall be kept in water for 30 min at 4° C (39° F) or 25° C (77° F) before testing, dependent upon the temperature at which the ductility is desired. The briquet with the clips attached shall then be placed in a ductility test machine filled with water at one of the above temperatures to a sufficient height to cover

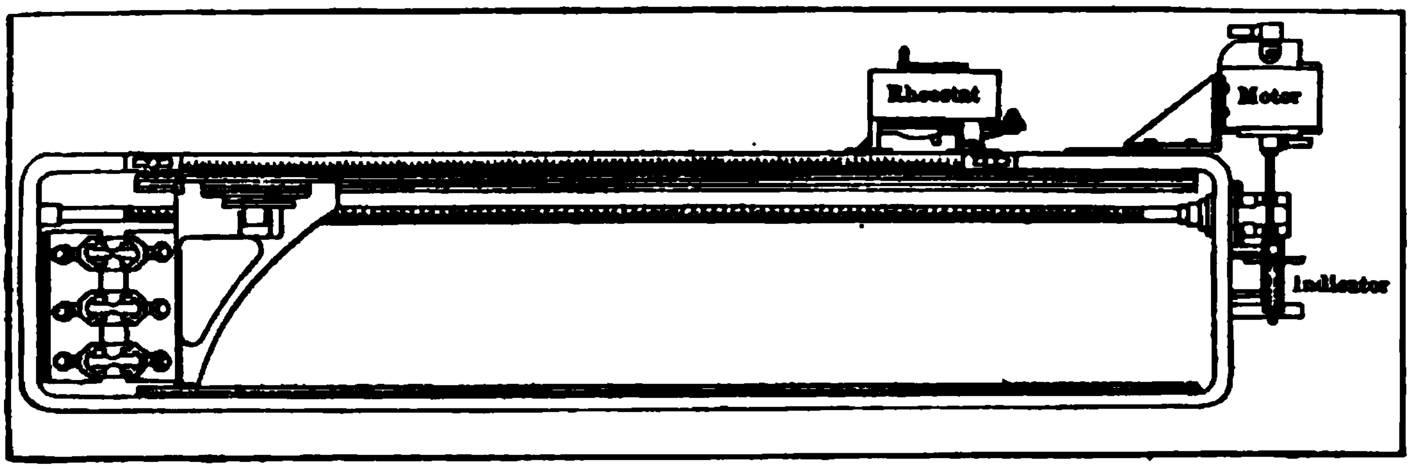

Fig. 38. Chew Ductility Machine

the briquet not less than 50 mm. This machine consists of a rectangular water-tight box, having a movable block working on a worm-gear from left to right. The left clip is held rigid by placing its ring over a short metal peg provided for this purpose; the right clip is placed over a similar rigid peg on the movable block. The movable block is provided with a pointer which moves along a centimeter scale. Before starting the test, the centimeter scale is adjusted to the pointer at zero. Power is then applied by the worm-gear pulling from left to right at the uniform rate of 5 cm per min. The distance, in centimeters, registered by the pointer on the scale at the time of rupture of the thread of asphalt cement shall be taken as the ductility of the asphalt cement."

Value of the Ductility Test. As ordinarily applied, the ductility test is of little value except as a means of identification when considered in connection with certain other tests and for control in the manufacture of certain types of bituminous materials. For a given penetration at 25° C (77° F), those materials which are most susceptible to temperature changes are the most ductile at 25° C (77° F). As for a given type of material ductility decreases with penetration, it follows that most materials with a high ductility at 25° C (77° F) show a very low ductility at 4° C (39° F). Materials which are but slightly susceptible to temperature changes, such as blown asphalts, as a rule have a low ductility at 25° C (77° F) but as their penetration at 4° C (39° F) is not so greatly changed neither is their ductility.

If the ductility test is considered as a measure of the stretch of the bituminous material when incorporated in a pavement, which stretch may be caused by contraction of the pavement, it would appear that high ductility at 25° C (77° F) should, in many cases, be undesirable because it represents low ductility at the low temperatures, which cause material contraction. As a matter of fact, it is more than doubtful if the test, as conducted, in any way represents the behavior of the comparatively thin films of material as they exist in a bituminous pavement. The theory has also been advanced that ductility is a measure of adhesiveness. Certainly those materials which appear to be most sticky at normal temperature show a high ductility at normal temperature, but if the theory holds true their adhesiveness falls off more markedly with decrease in temperature than does the initial adhesiveness of materials with a normally low ductility. Also, if this theory is unqualifiedly admitted, it would seem reasonable to conclude that the adhesiveness of an asphalt cement of, say, 60 penetration is less than that of the same type of asphalt cement of 150 penetration. The binding strength of the former is, however, known to be higher. From the above it is evident that correct interpretation of the ductility test, except as a means of identification and control, is no simple matter. In general, for a given type of bituminous material, the ductility decreases as the specific gravity increases.

40. Melting Point

Conditions Affecting the Melting Point Determination. As bituminous materials are not definite individual chemical compounds but mixtures of a great number of compounds, and as those which are ordinarily termed solids are not true solids but merely solid solutions, it follows that they can have no true melting point. In other words, pure bitumen which may be hard and brittle at normal temperature, if heated, will gradually become softer and softer until it is fluid and no critical temperature can be observed for its change from solid to liquid form. Any method of determining the melting point of bituminous materials is therefore purely arbitrary and gives purely arbitrary results. A great many methods have been devised for determining the melting point of these materials, but those perhaps most commonly used in connection with materials of interest in highway engineering are the cube method and the ring and ball method.

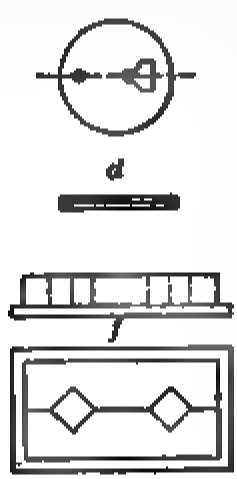

Fig. 34. Melting Point Apparatus for Cube Method

Cube Method. There are two variations to the cube method, one in which the cube of bituminous material is suspended in air and the other in which it is suspended in water. The latter is sometimes used for very soft materials which have a gravity greater than one such as the softer refined tars. Wherever possible, however, the air bath method is to be recommended This method is used by the U. S. O. P. R. and it has been recommended by the Spec. Com. Mat. Road Cons., Am. Soc. C. E. (13) for the determination of the melting point of tar products. The

melting point apparatus is shown in Fig. 34. The material to be examined is first melted in a spoon by the gentle application of heat until sufficiently fluid to pour readily. When heating, care should be taken that it suffer no appreciable loss by volatilization. It is then poured into a 0.5-in brass cubical mold *f* which has been amalgamated with mercury and which is placed on an amalgamated brass plate. The brass may be amalgamated by washing it first with a dilute solution of mercuric chloride or nitrate, after which the mercury is rubbed into the surface. By this means the bituminous material is, to a considerable extent, prevented from sticking to the sides of the mold. The hot material should slightly more than fill the mold, and, when cooled, the excess may be cut off with a hot spatula. After cooling to room temperature, the cube is removed from the mold and fastened upon the lower arm of a No. 12 wire (Brown & Sharpe gauge), *e* bent at right angles and suspended beside a thermometer in a covered Jena glass beaker, *b*, of 400 cu cm capacity, which is placed in a water bath, or, for high temperatures, a cottonseed-oil bath. The wire should be passed thru the center of two opposite faces of the cube, which is suspended with its base 1 in above the bottom of the beaker. The water or oil bath consists of an 800-cu cm low-form Jena glass beaker *a*, suitably mounted for the application of heat from below. The beaker in which the cube is suspended is of the tall-form Jena type without lip. The metal cover has two openings as shown in *d*. A cork, thru which passes the upper arm of the wire, is inserted in one hole and the thermometer in the other. The bulb of the thermometer should be just level with the cube and at an equal distance from the side of the beaker. In order that a reading of the thermometer may be made, if necessary, at the point which passes thru the cover, the hole is made triangular in shape and covered with an ordinary object glass thru which the stem of the thermometer may be seen. Readings made thru this glass should be calibrated to the angle of observation, which may be made constant by always sighting from the front edge of the opening to any given point on the stem of the thermometer below the cover. After the test specimen has been placed in the apparatus, the liquid in the outer vessel is heated in such a manner that the thermometer registers an increase of 5° C (9° F) per min. The temperature at which the bituminous material touches a piece of paper placed in the bottom of the beaker is taken as the melting point. Determinations made in the manner described should not vary more than 2° C (3.6° F) for different tests of the same material. At the beginning of this test the temperature of both bitumen and bath should be approximately 25° C (77° F).

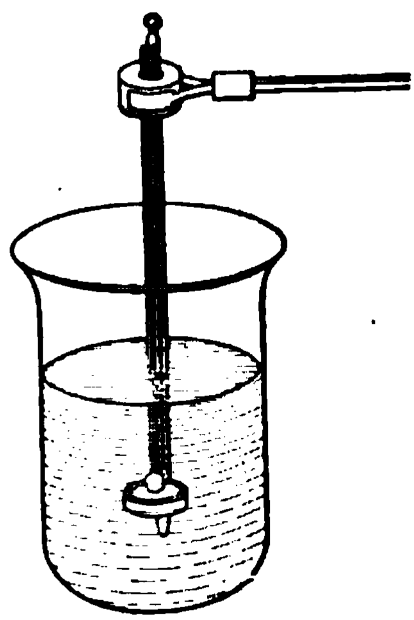

Fig. 35. Melting Point Apparatus for Ring and Ball Method

Ring and Ball Method, Am. Soc. Test. Mat. In 1916 Com. D-4 of the Am. Soc. Test. Mat. and in 1918 the Spec. Com. Mat. Road Cons., Am. Soc. C. E. (13) recommended the following method for determining the softening point of bituminous materials other than tar products, for adoption as standard:

"Definition. Ring and ball method.

"Apparatus. Brass ring 5/8 in in diameter, 1/4 in deep, 3/32 in wall, suspended 1 in above bottom of beaker. Steel ball 3/8 in in diameter, weighing between 3.45 g and 3.50 g. Standardized thermometer. Glass beaker, approximately 600 cu cm capacity. See Fig. 35.

"Operation. Carefully melt sample and fill ring with material to be tested. Remove any excess. Place ball in center of ring and suspend in beaker containing approximately 400 cu cm of water at a temperature of 5° C (41° F). Arrange thermometer bulb within ½ in of sample and at same level. Apply heat uniformly over bottom of beaker in quantity sufficient to raise temperature 5° C (9° F) per min. Record temperature at starting test and every minute thereafter until test is completed. Rate of heating is very important. Softening point is temperature at which specimen has dropped 1 in. Successive tests should average within 3° C (5.4° F). For temperatures above 95° C (203° F), glycerine should be used instead of water."

Value of the Melting Point Determination. The melting point of a bituminous material is directly related to its hardness and brittleness but the relations are not the same for all types of materials. Like most of the other physical tests it may serve as a method of control and identification. For a given type of material the melting point usually rises as the specific gravity increases and as the penetration decreases. A partly blown petroleum residuum may, however, be manipulated so as to obtain a number of combinations of penetration and melting point. Thus, if a fluid petroleum residuum is blown to a given penetration, its melting point will be much higher than tho a residuum of the same penetration had been produced by distillation alone. Intermediate melting points for that penetration may therefore be secured by varying the amount of distillation prior to or with the blowing process. High melting-point materials are as a rule less susceptible to the ordinary temperature changes than are low melting-point products. When used as a seal coat or as a filler they are therefore less likely to bleed in warm weather.

41. Flash and Burning Points

Open-Cup Method. For ordinary work the open-cup method of determining the flash and burning points of bituminous materials is sufficiently accurate. For this purpose a Cleveland or Tagliabue Oil Tester, as shown in Fig. 36, is used. Such a tester consists of a brass water or oil bath *a* resting upon a stand *b* and heated by means of a Bunsen burner. The oil to be tested is placed in the brass cup *c* and a thermometer adjusted so that its bulb is completely covered with the material. For low-flashing products the outer bath is filled with water or cottonseed oil, but for high-flashing products the space is left empty. The method of making the test is similar to that described under the closed-cup method.

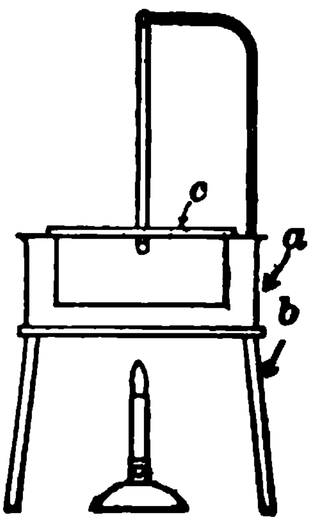

Fig. 36 Open-Cup Oil Tester

Closed-Cup Method. As determinations of flash points are subject to closer check in a closed cup than in an open cup, the closed-cup method is to be preferred for accurate work and has been recommended by the Spec. Com. Mat. Road Cons., Am. Soc. C. E. (13). For this purpose the New York State Board of Health Oil Tester, as shown in Fig. 37, is ordinarily used in the examination of bituminous materials for use in highway engineering. This instrument consists of a copper oil cup *a* of about 300 cu cm capacity, which is heated in a water or oil bath *b* by a small Bunsen flame. The cup is provided with a glass cover *c*, carrying a thermometer *d* and a hole *e* for inserting the testing flame.

The testing flame is obtained from a jet of gas passed thru a piece of glass tubing, and should be about 5 mm in length.

The FLASH TEST is made as follows: The oil-cup should first be removed and the bath filled with water or cottonseed oil. The oil may always be used and is necessary for bituminous materials flashing at a temperature of over 100° C (212° F). The oil cup should be replaced and filled with the material to be tested to within 3 mm of the flange joining the cup and the vapor chamber above. The glass cover is then placed on the oil cup and the thermometer so adjusted that its bulb is just covered by the bituminous material. The Bunsen flame should be applied in such a manner that the temperature of the material in the cup is raised at the rate of about 5° C (9° F) per min. From time to time the testing flame is inserted in the opening in the cover to about half way between the surface of the material and the cover. The appearance of a faint bluish flame over the entire surface of the bituminous material shows that the flash point has been reached and the temperature at this point is taken.

The BURNING POINT of the material may now be obtained by removing the glass cover and replacing the thermometer in a wire frame. The temperature is raised at the same rate and the material tested as before. The temperature at which the material ignites and burns is taken as the burning point. At the conclusion of this test the flame should not be blown out for danger of splashing the hot material, but a metal cover or extinguisher should be placed over the ignited material.

The Flash and Burning Point Determinations Are of Value as a quick means of differentiating heavy crude and fluid residual products. All crude fluid bituminous materials have much lower flash points than residuals, the flash points of which increase as the temperature of distillation at which they are produced increases. In general, for a given type of material, the lower its specific gravity the lower its flash point. Cut-back products produced with a light volatile flux necessarily show a lower flash point than do straight residuals of the same viscosity, float test, or penetration, and are thus quickly indicated. The flash point of asphalt cements which are not cut-back products almost invariably exceeds 163° C (325° F) and is usually higher than 200° C (392° F). Under certain working conditions the temperature at which a material flashes may be considered as a danger point and in specifications the flash point limit is often placed at a higher temperature than that to which it will be necessary to heat the material while being used. Sometimes the flash and burning points of a material are quite close together, and in other cases they are quite far apart. The relation of flash to burning point is largely dependent upon the amount present in the material of that volatile constituent which first flashes. The flash and burning points of a mixture of hydrocarbons are seldom those of the most volatile constituents as the presence of the heavier bodies tends to retard volatilization of the lighter. The flash and burning points of two or more constituents of a mixture are not additive so that those of the mixture can-

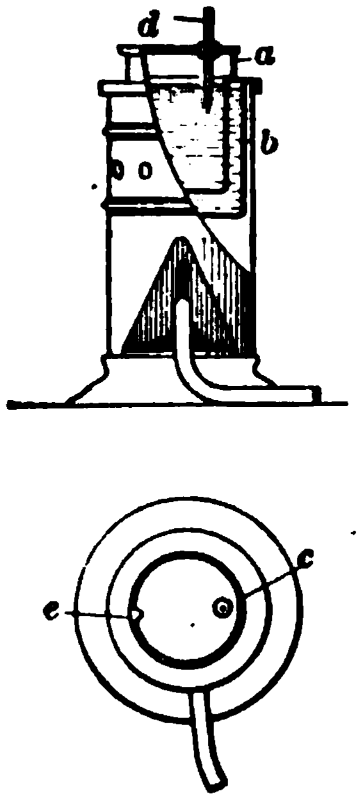

Fig. 87. N. Y. State Board of Health Oil Tester

not be predetermined. The mixture should, however, show flash and burning points lying between those of the constituents. In reports of results and in specifications, the type of cup should be indicated, as the open cup usually gives considerably higher results than the closed cup in which the evolved vapors are more or less confined.

42. Volatilization Tests

The New York Testing Laboratory Oven is most commonly used in making volatilization or evaporation tests on bituminous materials. The size and shape of oven, its method of heating, and ventilation are important factors in connection with the volatilization test, and no entirely satisfactory type has as yet been designed. Uniform temperature is also extremely important and some type of thermo-regulator is required to control the temperature. The New York Testing Laboratory Oven equipped with thermo-regulator is shown in Fig. 38. This oven is cylindrical in shape and consists of an inner compartment fitted with a circular perforated metal shelf for holding the samples under test. This shelf should be covered with a heavy perforated sheet of asbestos to minimize the direct conduction of heat from the metal to the sample holders. A cylindrical outer compartment equipped with a hinged cover at the top is fitted over the inner compartment leaving an air space between the two. The oven is heated from below by means of a ring burner with perforations systematically placed so as to equalize the flames as nearly as possible. The top or cover of the oven contains a number of openings to allow of air circulation and the insertion of thermometers and gas regulator. The oven is usually equipped with a fan or air stirrer below the shelf which may be operated from a pulley connected to a shaft which extends upward thru the center opening in the top. Use of the fan during the test, however, has been generally discontinued. A gas regulator is inserted thru one of the openings in the top of the oven, and two thermometers are inserted thru others so that their bulbs are at the same level as the samples under test. The bulb of one of these thermometers is in the air and that of the other is placed in a bath of heavy non-volatile oil. The latter serves to show the temperature of the samples during test while the former gives prompt warning of any sudden changes in temperature due to draught, irregularities in gas pressure, etc. The gas regulator should be adjusted so that the thermometer in the oil is maintained at the correct temperature of the test.

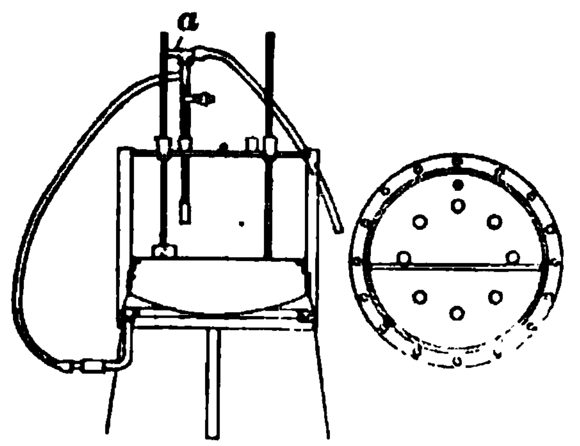

Fig. 38. N. Y. Testing Laboratory Oven

Am. Soc. Test. Mat. Method. In 1916 the Am. Soc. Test. Mat. adopted, and in 1918 the Spec. Com. Mat. Road Cons. Am. Soc. C. E. (13) recommended the following test for loss on heating of oils and asphaltic compounds for adoption as standard: "The amount lost by oils and asphaltic compounds when they are heated in an oven at a temperature of 163° C (325°F) plus or minus 1° C (2° F) shall be determined by heating 50 g of the water-free substance contained in a flat-bottomed dish, the inside dimensions of which are approximately 55 mm (2 3/16 in) in diameter by 35 mm (1 3/8 in)

deep (3-oz Gill style ointment box, deep style) for 5 hr. The oven in which the substance is heated shall be brought to the prescribed temperature before the sample is introduced, and the temperature of the sample under test shall be regarded as that of a similar quantity of the same material immediately adjoining it in the oven, in which the bulb of a standardized thermometer is immersed. The oven may be either of circular or rectangular

Fig. 39. Revolving Shelf for Volatilization Test

form and the source of heat either gas or electricity. The samples under test shall rest in the same relative position in a single row upon a perforated circular shelf 248 mm (9¾ in) in diameter, Fig. 39, suspended by a vertical shaft midway in the oven which is revolved by mechanical means at the rate of from 5 to 6 rev per min. Notes: If additional periods of heating are desired, it is recommended that they be made in successive increments of 5 hr each. If the residue after heating is to be tested for penetration, the sample should be thoroly mixed by stirring until it is cool, and thereafter manipulated in accordance with the directions of the standard test for penetration of bituminous materials."

Conditions Affecting the Volatilization Test. Besides the oven itself and the temperature employed, there are a number of other conditions that affect the volatilization test. The most important of these is the relation of exposed surface area to the volume of sample tested. This means that for a given diameter of container variable percentages of loss, by volatilization will occur for different volumes or weights of a given sample which is tested. This particularly true for materials that show a high loss under the test, and as the consistency of the residue is largely dependent upon the percentage of loss by volatilization, it follows that for a given temperature and time of test the penetration of the residue will vary with the relation of the diameter of the container and the weight of sample tested. It will be noted that in the two methods above described the diameter specified for the container is approximately the same, but that one method

specifies a 20 g sample while the other specifies a 50 g sample. In reporting results, therefore, it is customary to indicate the weight of sample tested as well as the temperature and time of test. The 20 g sample has been most commonly used for the harder grades of asphalt cements, but as this amount does not afford sufficient depth for a determination of the penetration of the residue obtained from the softer asphalt cements, a strong preference is being shown for the 50 g sample. Stirring the sample after the 3 and 4 hr period, as described in the preceding paragraph, is not common practice. It involves the weighing of a stirring rod for each sample. The ordinary procedure is to allow the test to run for five continuous hours.

Value of the Volatilization Test. The volatilization test at 163° C (325° F) is commonly made upon petroleum and asphalt products but seldom upon tar products. The temperature was originally selected as being that at which a refined asphalt is usually fluxed to produce an asphalt cement. With few exceptions, it may also be considered as the maximum allowable temperature to heat bituminous materials for direct use. Materials which are likely to be heated to this temperature should preferably show an open flash test which is higher. Asphalt cements of the consistency which is desired to be maintained after use should show a low loss under the volatilization test and the residue should not show an undue decrease in penetration or hardening as compared with the original sample. Carefully prepared asphalt cements of less than 100 penetration at 25° C (77° F) do not as a rule show a loss of over 1 or 2%, and the same is true of most fluxed native asphalts, altho those produced from Bermudez asphalt may run slightly higher. For such products it is customary to specify that the penetration of the residue at 25° C (77° F) shall be not less than 50% of that of the original material at 25° C (77° F). Heavy residual fluxes as a rule show a loss of less than 5% under this test. On the other hand, cut-back asphalts are supposed to show a relatively high loss and to harden materially when subjected to the volatilization test. Irrespective of the consistency of the original material, the residues from cut-back asphalts should show a penetration which is not materially higher than that which it is desired to maintain under service conditions. When testing fluxed products such as carpeting mediums the residue from the volatilization test may be subjected to the float test if too soft for its penetration to be determined. This is particularly valuable where the float test can be made upon both the original material and its residue. In some cases the volatilization test is made at other temperatures than 163° C (325° F). Thus the tendency of a material to harden very rapidly after use is shown by a test at 100°, 105° or 110° C (212°, 221° or 230° F). If the test is to be made upon a tar product a relatively low temperature should be used, as 163° C (325° F) is unnecessarily severe for tars, owing to the fact that it is never necessary to heat them to this temperature during use and if they are so heated they are apt to be seriously injured. In general, for a given type of residual product, the loss by volatilization decreases with increase in specific gravity, flash point, and specific viscosity or float test, and decreases in penetration if it is a semisolid or solid.

Evaporation Test for Determining Percent of Asphalt. An evaporation or volatilization test has been used to some extent in determining the so-called asphalt content of fluid petroleum products. In such a test a weighed quantity of the material is heated in an open dish. At intervals the sample is allowed to cool and its penetration taken at 25° C (77° F). When the residue shows a penetration of approximately 100 it is weighed. The weight

percentage of such residue is then reported as the asphalt content of the material. In some cases a maximum temperature of 260° C (500° F) is specified. At considerably lower temperatures, however, chemical changes are often produced in the material tested and the residue does not then represent asphalt which was present in the original material but asphalt which is actually manufactured by the test itself. Such asphalt would in most cases never be developed under ordinary conditions of use and the term asphalt content as applied to the results of this test is therefore misleading. In 1914 the Committee on "Standard Tests for Road Materials" of the Am. Soc. Test. Mat. recommended that the use of the term asphalt content be discontinued. The test itself is inaccurate and greatly affected by conditions which are seldom taken into account. Thus the percentage of residue will vary with the temperature employed, and the frequency of stirring the heated sample if it is stirred, as oxidation is largely responsible for the hardening. A higher percentage of residue of a given penetration may usually be obtained by frequent stirring than by undisturbed volatilization, owing to more intimate contact of the oxygen of the air with the mass of material.

43. Distillation Tests

Am. Soc. Test. Mat. Method. In 1916 the following method for the distillation of bituminous materials suitable for road treatment was adopted as standard by the Am. Soc. Test. Mat., and in 1918 the Spec. Com Mat. Road. Cons., Am. Soc. C. E. (13) recommended
llation tests of complicated hydro-

f necessary, until all the water has
The distillate is collected in a 200 cu cm separatory funnel with the tube cut off close to the stopcock. When all the water has been driven over and the distillate has settled out, the water is drawn off and the oils returned to the residue in the still. The contents of the still shall have cooled to below 100° C (212° F) before the oils are returned, and they shall be well stirred and mixed with the residue.

"Apparatus. The apparatus shall consist of the following standard parts:

Fig. 40. Distillation Apparatus

"Flask. The distillation flask shall be a 250 cu cm Engler distilling flask, having the following dimensions:

Diameter of bulb	8.0 cm
Length of neck	15.0 cm
Diameter of neck	1.7 cm
Surface of material to lower side of tubulature	11.0 cm
Length of tubulature	15.0 cm
Diameter of tubulature	0.9 cm
Angle of tubulature	75°

A variation of 3% from the above measurements will be allowed.

"Thermometer. The thermometer shall conform to the following requirements:

"It shall be made of thermometric glass of a quality equivalent to suitable grades of Jena or Corning make. It shall be thoroly annealed. It shall be filled above the mercury with inert gas which will not act chemically on or contaminate the mercury. The pressure of the gas shall be sufficient to prevent separation of the mercury column at all temperatures of the scale. There shall be a reservoir above the final graduation large enough so that the pressure will not become excessive at the highest temperature. The thermometer shall be finished at the top with a small glass ring or button suitable for attaching a tag. Each thermometer shall have for identification the maker's name, a serial number, and the letters 'A. S. T. M. Distillation.'

"The thermometer shall be graduated from 0° to 400° C at intervals of 1° C. Every fifth graduation shall be longer than the intermediate ones, and every tenth graduation beginning at zero shall be numbered. The graduation marks and numbers shall be clear-cut and distinct.

"The thermometer shall conform to the following dimensions:

Total length, maximum	385 mm;	
Diameter of stem	7 mm;	permissible variation, 0.5 mm;
Diameter of bulb, minimum	5 mm;	and shall not exceed diameter of stem;
Length of bulb	12.5 mm;	permissible variation, 2.5 mm;
Distance of 0° to bottom of bulb	30 mm;	permissible variation, 5 mm;
Distance from 0° to 400°	295 mm;	permissible variation, 10 mm.

"The accuracy of the thermometer when delivered to the purchaser shall be such that when tested at full immersion the maximum error from 0° to 200° C shall not exceed the following:

From 0° to 200° C	0.5° C;
From 200° to 300° C	1.0° C;
From 300° to 375° C	1.5° C.

"The sensitiveness of the thermometer shall be such that when cooled to a temperature of 74° C below the boiling point of water at the barometric pressure, at the time of test, and plunged into free flow of steam, the meniscus shall pass the point 10° C below the boiling point of water in not more than 6 sec.

"The thermometer shall be set up as for the distillation test, using water, naphthalene, and benzophenone as distilling liquids. The correctness of the thermometer shall be checked at 0° and 100° C after each third distillation until seasoned."

"Condenser. The condenser tube shall have the following dimensions:

Adaptor	70 mm
Length of straight tube	185 mm
Width of tube	12 to 15 mm
Width of adaptor end of tube	20 to 25 mm

"Stands. Two iron stands shall be provided, one with a universal clamp for holding the condenser, and one with a light grip arm with a cork-lined clamp for holding the flask.

"Burner and Shield. A Bunsen burner shall be provided, with a tin shield 20 cm long by 9 cm in diameter. The shield shall have a small hole for observing the flame.

"Cylinders. The cylinders used in collecting the distillate shall have a capacity of 25 cu cm and shall be graduated in tenths of a cubic centimeter.

"Setting up the Apparatus. The apparatus shall be set up as shown in Fig. 40, the thermometer being placed so that the top of the bulb is opposite the middle of the tubulature. All connections should be tight.

"Method. One hundred cubic centimeters of the dehydrated material to be tested shall be placed in a tared flask and weighed. After adjusting the thermometer, shield, condenser, etc, the distillation is commenced, the rate being so regulated that 1 cu cm passes over every minute. The receiver is changed as the mercury column just passes the fractionating point. The following fractions should be reported: Start of distillation to 110° C; 110° to 170° C; 170° to 235° C; 235° to 270° C; 270° to 300° C; residue. To determine the amount of residue, the flask is weighed again when distillation is complete. During the distillation the condenser tube shall be warmed when necessary to prevent the deposition of any sublimate. The percentages of fractions should be reported both by weight and by volume."

Standard Creosoters' Distillation Test. While the preceding method is suitable for use in connection with the distillation of all types of bituminous materials, the following method as given in Bulletin 65 of the American Railway Engineering and Maintenance of Way Association has been widely used in the examination of creosoting oils. The apparatus as shown in Fig. 41 consists of a glass-stoppered retort having a capacity of approximately 8 oz up to the bend of the neck when the bottom of the retort and the mouth of the off-take are in the same plane. A nitrogen-filled mercury thermometer graduated in full degrees Centigrade is used for recording the temperatures. The following is further specified: "The bulb of the retort and at least 2 in of the neck must be and remain covered with a shield of heavy asbestos paper, shaped as shown in diagram, during the entire process of distillation, so as to prevent heat radiation, and between the bottom of the retort and the flame of the lamp or burner two sheets of wire gauze, each 20-mesh fine and at least 6 in square, must be placed. It is also recommended that the flame be protected against air currents. An ordinary tin can, from which a portion of the bottom and all of the top have been removed, placed on a support attached to the burner, as shown in diagram, has been found to answer the purpose. Before beginning the distillation the retort should be carefully weighed and exactly 100 g of the oil placed therein, the same being weighed in the retort.

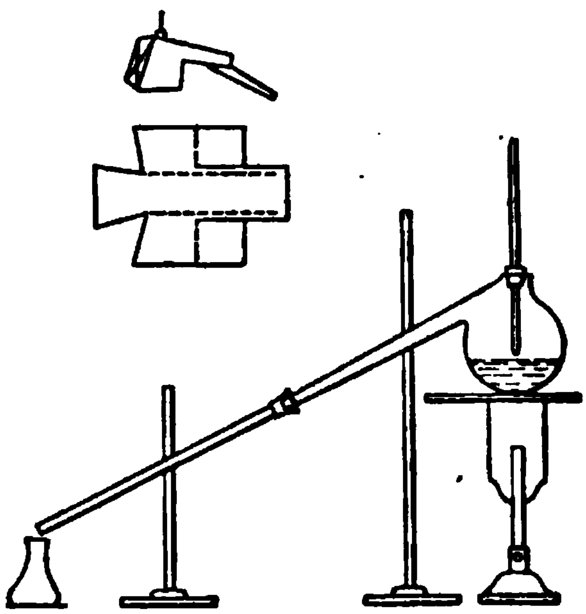

Fig. 41. Standard Creosoters' Distillation Apparatus

The thermometer should be inserted in the retort with the lower end of the bulb ½ in from the surface of the oil, and the condensing tube attached to the retort by a tight cork joint. The distance between the bulb of the thermometer and the end of the condensing tube should not be less than 20 nor more than 24 in, and during the progress of the distillation the thermometer must remain in its original position. The distillates should be collected in weighed bottles and all fractions determined by weight. Reports are to be made on the following fractions: 0° to 170° C; 170° to 200° C; 200° to 210° C; 210° to 235° C; 235° to 270° C; 270° to 315° C; 315° to 355° C. For practical purposes there will be no need of reporting on all of these fractions. It will be sufficient to report on the fractions as follows: below 200° C; 200° to 210° C; 210° to 235° C; 235° to 315° C; above 315° C. Reports are to be made on individual fractions. In making such reports, it is to be distinctly understood that those fractions do not necessarily refer to individual compounds. In other words, the fractions between 210° and 235° C will not necessarily be all naphthalene, but will probably contain a number of other compounds. The distillation should be a continuous one and should take about 45 min. When any measurable quantity of water is present in the oil, the distillation should be stopped, the oil separated from the water, and returned to the retort, when the distillation should be recommenced and the previous readings discarded."

Value of Distillation Test. The distillation test as applied to tars is valuable both as a means of ascertaining their method of preparation and suitability for a given purpose. In this connection it takes the place of the volatilization test, which is usually restricted to the examination of petroleum and asphalt products. All crude tars contain water and the appearance of water in the distillate therefore indicates a crude material, especially if accompanied by an appreciable quantity of light oil. Heavy refined tars which have become contaminated with water show a sudden rise in distillation temperature after the water has been removed. The presence of high percentages of naphthalene is indicated by the proportion of the various distillates which solidify upon cooling. In this connection it is always well to note the character of each fraction obtained. The extent of distillation in the manufacture of the original material is indicated by the temperature at which distillation commences in the test and the relative quantities of the fractions obtained. Cut-back products usually show an abnormal amount of some given fraction as compared to the amount that would be obtained from a straight distilled residue of the same consistency. After the distillation test is completed it is often of interest to determine the melting point of the pitch residue which, if obtained by distillation to 300° C, should seldom e ceed 75° C. Tar distillates are soluble in dimethyl sulphate while petroleum and asphalt distillates are not. Mixtures of tar with petroleum or asphalt products are therefore detected by the presence of an appreciable quantity of distillate, which when shaken up with an excess of dimethyl sulphate shows a separation of insoluble material. A fraction distilling above 300° C is usually selected for the dimethyl sulphate test (34a) when the presence of a petroleum or asphalt product is suspected. Different tars vary so in character that it is difficult to define the exact relation of the distillation test to other tests. In general, however, for a given type of residual tar the percentage of total distillate decreases as the specific gravity and viscosity or float test increases.

44. Total Bitumen

Carbon Disulphide. According to standard definition, all bitumen is soluble in carbon disulphide. The percent of total bitumen in a bituminous material is therefore determined by its solubility in carbon disulphide. This solvent is an etherial mobile liquid which is extremely inflammable and should be handled with great care. It is very volatile and when mixed with air its vapors spontaneously ignite at a temperature slightly higher than that of live steam. When used for testing bituminous materials extraordinary precautions should therefore be taken to prevent possible fire or explosion.

The Ordinary Filtration Method substantially as described by Hubbard and Reeve (25b) and recommended by the Spec. Com. Mat. Road Cons., Am. Soc. C. E. (13), is as follows:

This test consists in dissolving the bituminous material in carbon disulphide and recovering any insoluble matter by filtering the solution thru an asbestos felt. The form of Gooch crucible best adapted for the determination is 4.4 cm wide at the top, tapering to 3.6 cm at the bottom, and is 2.5 cm deep. For preparing the felt the necessary apparatus is arranged as shown in Fig. 42, in which *a* is the filtering flask, *b* a rubber stopper, *c* the filter tube, and *d* a section of rubber tubing which tightly clasps the Gooch crucible *e*. The asbestos is cut with scissors into pieces not exceeding 1 cm in length, after which it is shaken up with just sufficient water to pour easily. The crucible is filled with the suspended asbestos, which is allowed to settle for a few moments. A light suction is then applied to draw off all the water and leave a firm mat of asbestos in the crucible. More of the suspended material is added, and the operation is repeated until the felt is so dense that it scarcely transmits light when held so that the bottom of the crucible is between the eye and the source of light. The felt should then be washed several times with water, and drawn firmly against the bottom of the crucible by an increased suction. The crucible is removed to a drying oven for a few minutes, after which it is ignited at red heat over a Bunsen burner, cooled in a dessicator and weighed. From 2 to 3 g of bituminous material or about 10 g of an asphalt topping or rock asphalt is now placed in the Erlenmeyer flask, which has been previously weighed, and the accurate weight of the sample is obtained. One hundred cubic centimeters of c. p. carbon disulphide is poured into the flask in small portions, with continual agitation, until all lumps disappear and nothing adheres to the bottom. The flask is then corked and set aside for 15 min. After being weighed, the Gooch crucible containing the felt is set up over the dry pressure flask, as shown in Fig. 42, and the solution of bitumen in carbon disulphide is decanted thru the felt without suction by gradually tilting the flask, with care not to stir up any precipitate that may have settled out. At the first sign of any sediment coming out, the decantation is stopped and the filter allowed to drain. A small amount of carbon disulphide is then washed down the sides of the flask, after which the precipitate is brought upon the felt and the flask scrubbed, if necessary, with a feather or "policeman," to remove all adhering material. The contents of the crucible are washed with carbon disulphide until the washings run colorless. Suction is then applied until there is practically no odor of carbon disulphide in the crucible, after which

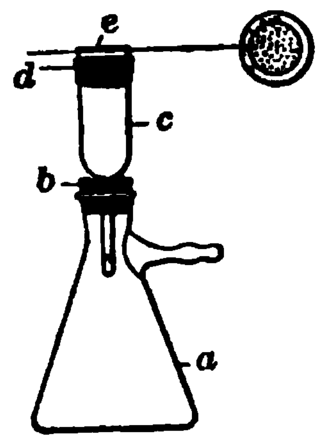

Fig. 42. Filtration Apparatus

the outside of the crucible is cleaned with a small amount of the solvent. The crucible and contents are dried in a hot-air oven at 100° C (212° F) for about 20 min, cooled in a desiccator, and weighed. If any appreciable amount of insoluble matter adheres to the flask, it should also be dried and weighed, and any increase over the original weight of the flask should be added to the weight of insoluble matter in the crucible. The total weight of insoluble material may include both organic and mineral matter. The former, if present, is burned off by ignition at a red heat until no incandescent particles remain, thus leaving the mineral matter or ash, which can be weighed on cooling. The difference between the total weight of material insoluble in carbon disulphide and the weight of substance taken equals the total bitumen, and the percentage weights are calculated and reported as total bitumen, and organic and inorganic matter insoluble, on the basis of the weight of material taken for analysis. This method is quite satisfactory for straight oil and tar products, but where native asphalts are present it will sometimes be found practically impossible to retain all of the finely divided mineral matter on an asbestos felt. It is, therefore, generally more accurate to obtain the result for total mineral matter by direct ignition of a 1 g sample in a platinum crucible or to use the result for ash obtained in the fixed carbon test. The total bitumen is then determined by deducting from 100% the sum of the percentages of total mineral matter and organic matter insoluble. If the presence of a carbonate mineral is suspected, the percentage of mineral matter may be most accurately obtained by treating the ash from the fixed carbon determination with a few drops of ammonium carbonate solution, drying at 100° C (212° F), then heating for a few minutes at a dull red heat, cooling, and weighing again. When difficulty in filtering is experienced, as when Trinidad asphalt is present in any amount, a period of longer subsidence than 15 min is necessary, and the following standard method adopted in 1911 by the Am. Soc. Test. Mat. is recommended.

Am. Soc. Test. Mat. Method. " After drying, from 2 to 15 g, as may be necessary to insure the presence of 1 to 2 g of pure bitumen, are weighed into a 150-cu cm tared Erlenmeyer flask, and treated with 100 cu cm of carbon disulphide. The flask is then loosely corked and shaken from time to time until all large particles of the material have been broken up. It is then set aside for 48 hr to settle. The solution is decanted into a similar flask that has been previously weighed. As much of the solvent is poured off as possible without disturbing the residue. The contents of the first flask are again treated with fresh carbon disulphide, shaken as before, and put away with the second flask for 48 hr to settle.

" The liquid in the second flask is then carefully decanted upon a weighed Gooch crucible, 3.2 cm in diameter at the bottom, fitted with an asbestos filter, and the contents of the first flask are similarly treated. The asbestos filter is made of ignited long-fiber amphibole, packed in the bottom of a Gooch crucible to the depth of not over ⅛ in. In filtering, no vacuum is to be used and the temperature is to be kept between 20° and 25° C. After passing the liquid contents of both flasks thru the filter, the residue on the filter is thoroly washed, and the residues remaining in them are shaken with more fresh carbon disulphide and allowed to settle for 24 hr, or until it is seen that a good subsidation has taken place. The solvent in both flasks is then again decanted thru the filter, and the residues remaining in them are washed until the washings are practically colorless. All washings are to be passed thru the Gooch crucible.

"The crucible and both flasks are then dried at 125° C and weighed. The filtrate containing the bitumen is evaporated, the bituminous residue burned, and the weight of the ash thus obtained added to that of the residue in the two flasks and the crucible. The sum of these weights deducted from the weight of substance taken gives the weight of soluble bitumen."

Centrifugal Method. A number of centrifugal methods have been devised for the extraction and determination of bitumen in bituminous aggregates. No one method is ideal for all conditions, but the following method, as described by Hubbard and Reeve (25b) is of particular interest in connection with the determination of total bitumen in coarse bituminous aggregates. It is also useful for the purpose of recovering the extracted bitumen and aggregate for subsequent examination. The apparatus used is shown in Fig. 43.

It consists of a 1/8 h.p. 1100 rev per min vertical shaft electric motor *a* with the shaft projecting into the cylindrical copper box *b*, the bottom of which is so inclined as to drain to the spout *c*. A 3/16 in circular brass plate 9½ in in diameter is shown in *d*, and upon this rests the sheet-iron bowl *e*, which is 8½ in in diameter by 2 5/16 in high, and has 2 in circular hole in the top. Fastened to the inner side of the bowl is the brass cup *f*, having a circle of 1/8 in holes for the admission of the solvent, and terminating in the hollow axle, which fits snugly thru a hole at the center of the brass plate. The bowl may be drawn firmly against a felt-paper ring *g*, ¾ in wide, by means of the 2½ in milled nut *h*, for which the hollow axle is threaded for a distance of ¾ in directly below the upper surface of the plate. The axle fits snugly over the shaft of the motor, to which it is locked by a slot and cross pin *i*. The aggregate is prepared for analysis by heating it in an enamelware pan on the hot plate until it is sufficiently soft to be thoroly disintegrated by means of a large spoon. Care must be taken, however, that the individual particles are not crushed. If a section of pavement is under examination, a piece weighing somewhat over 1 kg may be cut off with hammer and chisel. The disintegrated aggregate is then allowed to cool, after which a sufficient amount is taken to yield on extraction from 50 to 60 g of bitumen. It is placed in the iron bowl and a ring ¾ in wide, cut from the felt paper, is fitted on the rim, after which the brass plate is placed in position and drawn down tightly by means of the milled nut. If the bitumen is to be recovered and examined, the felt ring should be previously treated in the empty extractor with a couple of charges of carbon disulphide in order to remove any small amount of grease or rosin that may be present altho a proper grade of felt should be practically free from such products. The bowl is now placed on the motor shaft and the slot and pin are carefully locked. An empty bottle is placed under the spout and 150 cu cm of carbon disulphide is poured into the bowl thru the small holes. The cover is put on the copper box and, after allowing the material to digest for a few minutes, the motor is started, slowly at first in order to permit the aggregate to distribute uniformly. The speed should then be increased sufficiently by means of the regulator to cause the dissolved bitumen to flow from the spout in a thin stream. When the first charge has drained, the motor is stopped and a

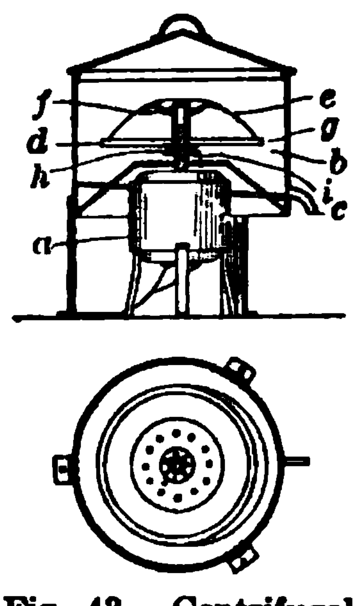

Fig. 43. Centrifugal Extractor

fresh portion of disulphide is added. This operation is repeated from four to six times with 150 cu cm of disulphide. With a little experience the operator can soon gage exactly what treatment is necessary for any given material. When the last addition of solvent has drained off, the bowl is removed and placed with the brass plate uppermost on a sheet of manila paper. The brass plate and felt ring are carefully laid aside on the paper and, when the aggregate is thoroly dry, it can be brushed on a pan of a large balance and weighed. The difference between this weight and the original weight taken shows the amount of bitumen extracted. The aggregate may then be tested as occasion requires.

Recovery of Extracted Bitumen. When it is desired to recover a sample of the extracted bitumen from a total bitumen determination, the solution of bitumen should be allowed to stand overnight in order to permit the settling of any fine mineral matter that is sometimes carried thru the felt ring in the extractor. The solution is then decanted into a flask and the solvent is driven off by means of heat from an incandescent lamp until the residue is of a thick sirupy consistency. Meanwhile the solvent is condensed and recovered in any suitable manner. The residue is poured into an 11-cm porcelain evaporating dish, and evaporated on a steam bath. The most scrupulous care must be taken at all times that no flames are in its immediate vicinity. Evaporation is carried on at a gentle heat, with continual stirring, until foaming practically ceases. It is advisable to have a large watch glass at hand to smother the flames quickly should the material ignite. As the foaming subsides, the heat of the steam bath may be gradually raised, and evaporation is continued until the bubbles beaten or stirred to the surface of the bitumen fail to give a blue flame or odor of sulphur dioxide when ignited by a small gas jet. The dish of bitumen should then be set in a hot-air oven maintained at 105° C (221° F) for about an hour after which it is allowed to cool. Its general character is noted and any tests for bitumens that are necessary are then made upon it.

Value of Total Bitumen Determination. The total bitumen determination is ordinarily made upon all types and grades of bituminous materials. There appears to be a strong tendency toward the purchase of bituminous materials upon a bitumen basis, as determined by their solubility in carbon disulphide. This is a perfectly rational practice in the case of liquid bituminous materials and bituminous cements, but not for bituminous aggregates such as asphalt block, rock asphalts, etc. All bituminous distillates produced by fractional distillation are completely soluble in carbon disulphide. Residual petroleum products should also be almost completely soluble. A small amount of still ash and extraneous organic matter is, however, usually present and an allowance of approximately 0.5% may therefore be made for total material insoluble in carbon disulphide. If the organic matter insoluble exceeds 0.5% there is strong indication that the petroleum has been cracked or locally overheated with possible resultant injury to the finished product. Native asphalts and products produced by fluxing the native asphalts ordinarily contain appreciable amounts of both mineral matter and organic matter insoluble in carbon disulphide. Gilsonite is one of the few exceptions to this rule. Where the exact percentage of total insoluble matter is known for a refined native asphalt, it is possible to compute with considerable accuracy the amount of such asphalt present in an asphalt cement produced by fluxing it. In such computation the petroleum flux is assumed to be completely soluble unless information to the contrary has been secured. Practically all of the material in tar prod-

ucts which is insoluble in carbon disulphide consists of organic matter or free carbon, and the percentage of free carbon is thus determined. Refined water-gas tars may be distinguished from refined coal tars of the same consistency by their relatively small percentage of free carbon. Gas-house coal tars, particularly those produced from horizontal retorts, may usually be distinguished from coke-oven tars and vertical retort tars by their relatively high percentage of free carbon. For refined tars of the same viscosity or float test, the specific gravity becomes higher as the solubility in carbon disulphide decreases. The same is true of asphalt cements produced from the same native asphalt if such asphalt contains insoluble material. As the solubility of a bituminous material in carbon disulphide is entirely dependent upon the non-bituminous constituents present, it is evident that no definite relations can be expressed between the physical and chemical properties of the actual bitumen present and the solubility of the material in this solvent. In other words, irrespective of specific gravity, consistency and other properties, all pure bitumen dissolves in carbon disulphide. An oily, greasy distillate is therefore just as much bitumen as a hard brittle residue. The total bitumen determination is particularly valuable as a laboratory control test in the preparation of bituminous aggregates. The serviceability of a bituminous aggregate is not only dependent upon the physical and chemical properties of the bituminous cement but also upon the percentage of such cement which is present. Too much may be almost as bad as too little, and the exact percentage should therefore be adjusted to meet the character and grading of the mineral aggregate which is used. When once the proper combination of bituminous cement and a given aggregate has been experimentally ascertained, the percent of bitumen as determined by test should, for different lots of the same bituminous aggregate, fall within comparatively narrow limits.

Rational Percent of Bitumen in Bituminous Aggregates. The determination of the percentage of bitumen in a bituminous material as ordinarily made is upon a weight basis. As a means of comparing different bituminous aggregates the weight basis is irrational unless the relations of weight to volume are the same for the mixtures compared. In any bituminous aggregate the volume of bitumen is a most important factor from the standpoint of covering capacity, thickness of film and, in some cases, the reduction of voids. In view of the rather wide variation in specific gravity of ordinary bituminous cements and mineral aggregates the volume method of comparison is the most rational. The volume or rational percent of bitumen in a bituminous aggregate may be determined by recovery of the bitumen after its extraction and determination upon a weight basis. The specific gravity of the recovered bitumen should be determined as well as that of the mineral aggregate. From this data the volume proportions of each are ascertained by dividing their weight percent by their respective specific gravity. These proportions transposed to total 100 are the rational or volume percentages of the constituents. The formula for expressing the rational percent of bitumen is as follows, where x represents the rational percent of bitumen, p the weight percent of bitumen, a the specific gravity of the bitumen, and b the specific gravity of the aggregate.

$$x = \frac{100\,p\,b}{pb + a\,(100 - p)}$$

The importance of the use of the rational percent of bitumen as a basis of comparison may be illustrated by considering two bituminous aggre-

gates which contain 6% by weight of bitumen and are practically identical in so far as the consistency of bitumen and grading of the aggregate are concerned. According to the ordinary interpretation of results of analysis, the two mixtures might be considered as equivalents. If, however, it is found that the first mix is composed of an aggregate with a specific gravity of 2.50 while the recovered bitumen shows a specific gravity of 1.17 and that the aggregate of the second mix has a specific gravity of 3.50 while the recovered bitumen shows a specific gravity of 0.960, the rational percent of bitumen would be found to differ greatly in the two mixes, as follows:

Constituents	Percent by Weight		Specific Gravity		Rational Proportion		Rational Percent
First Mix							
Aggregate	94	÷	2.50	=	37.6	=	88.0
Bitumen	6	÷	1.17	=	5.1	=	12.0
	100						100.0
Second Mix							
Aggregate	94	÷	3.50	=	26.9	=	81.0
Bitumen	6	÷	0.96	=	6.3	=	19.0
	100						100.0

From the results given in the last column it is evident that the first mix has a bitumen equivalent of about two-thirds that of the second mix, altho the percentages by weight are the same. The variation of 7% bitumen (which is the difference between the rational percentages 19 and 12) might, for a given type of aggregate, mean the difference between success and failure.

45. Naphtha Insoluble Bitumen (Asphaltenes)

Petroleum Naphthas are not definite chemical compounds, but are composed of a number of hydrocarbons which vary in character and quantity according to the petroleum from which they have been distilled. Their solvent action upon petroleum and asphalt products therefore varies greatly. Thus, naphthas produced from asphaltic petroleums, consisting mainly of naphthene and polymethylene hydrocarbons, are much more powerful solvents of the heavier asphaltic hydrocarbons than are the paraffin naphthas. Moreover, the solvent power of any given type of naphtha increases with its specific gravity. As the main object of the naphtha insoluble bitumen test is to separate the heavier hydrocarbons of an asphaltic nature from the other constituents, a light paraffin distillate is usually employed. One of 86° B gravity distilling between 40° and 65° C (104° and 149° F) has been used to a considerable extent, as has also an 88° B naphtha, the solvent power of which is approximately the same as that of the 86° B products. Heavier naphthas, such as 66° B and 72° B, are also less frequently used.

Method of Determination. The bitumen in petroleum and asphalt products which is insoluble in paraffin naphtha is known as asphaltenes. As the percentage of asphaltenes, as determined by test, is largely dependent upon the gravity and type of naphtha used as a solvent, a report of results should state the gravity of the naphtha and preferably its boiling point limits as well. The determination is not entirely satisfactory and investigations have been conducted with a view to finding some solvent of definite chemical composition which will satisfactorily replace naphtha and more nearly insure uniform results on the part of different analysts. Pentane, alcohol and ether have been suggested for this purpose but have not been generally used. The following method for determining bitumen insoluble

in paraffin naphtha is as described by Hubbard and Reeve (25b). This determination is made in the same general manner and with the same apparatus as described in the second paragraph of Art. 44 under THE ORDINARY FILTRATION METHOD for the determination of total bitumen, except that 100 cu cm of 86° B paraffin naphtha is employed as a solvent instead of carbon disulphide. Considerable difficulty is sometimes experienced in breaking up the heavy semisolid bituminous materials; the surface of the material is attacked, but it is necessary to remove some of the insoluble matter in order to expose fresh material to the action of the solvent. It is, therefore, advisable to heat the sample after it is weighed, allowing it to cool in a thin layer around the lower part of the flask. If difficulty is still experienced in dissolving the material, a rounded glass rod will be found convenient for breaking up the undissolved particles. Not more than one-half of the total amount of naphtha required should be used until the sample is entirely broken up. The balance of the 100 cu cm is then added, and the flask is twirled a moment in order to mix the contents thoroly, after which it is corked and set aside for 30 min. In making the filtration the utmost care should be exercised to avoid stirring up any of the precipitate, in order that the filter may not be clogged and that the first decantation may be as complete as possible. The sides of the flask should then be quickly washed down with naphtha, and, when the crucible has drained the bulk of insoluble matter is brought upon the felt. Suction may be applied when the filtration by gravity almost ceases, but should be used sparingly, as it tends to clog the filter by packing the precipitate too tightly. The material on the felt should never be allowed to run entirely dry until the washing is completed, as shown by the colorless filtrate. When considerable insoluble matter adheres to the flask, no attempt should be made to remove it completely. In such cases the adhering material is merely washed until free from soluble matter, and the flask is dried with the crucible at 100° C (212° F) for about 1 hr, after which it is cooled and weighed. The percentage of bitumen insoluble is reported upon the basis of total bitumen taken as 100. The difference between the material insoluble in carbon disulphide and in the naphtha is the bitumen insoluble in the latter. Thus, if in a certain instance it is found that the material insoluble in carbon disulphide amounts to 1% and that 10.9% is insoluble in naphtha, the percentage of bitumen insoluble would be calculated as follows:

$$\frac{\text{BITUMEN INSOLUBLE IN NAPHTHA}}{\text{TOTAL BITUMEN}} = \frac{10.9 - 1}{100 - 1} = \frac{9.9}{99} = 10\%$$

Value of Naphtha Insoluble Bitumen Determination. While the class of bodies known as asphaltenes in petroleum and asphalt products are of variable nature, it may be said that in general they tend to give body and consistency as well as cementitiousness to the materials in which they occur. Thus, the native asphalts carry a high percentage of asphaltenes while the fluid native bitumens or petroleums carry a relatively low percentage. Paraffin petroleums contain less than asphaltic petroleums, and petroleum distillates, which possess no cementitiousness, contain none at all. Upon distillation of a petroleum the asphaltenes tend to concentrate in the residuum, and under certain conditions new asphaltenes are actually formed. The blowing process, by causing what is known as nucleus condensation of certain of the lighter hydrocarbons, forms asphaltenes which are directly responsible for the gradual change of the fluid to a semisolid or a solid.

Irrespective of their method of manufacture, asphalt cements of a given penetration at 25° C (77° F) usually carry asphaltenes within comparatively narrow percentage limits and at least for a given type of asphalt cement the penetration is found to decrease as the percentage of asphaltenes increases. The percentage of asphaltenes is usually additive and, for mixtures, may be calculated with reasonable accuracy from the amounts present in the individual constituents of the mixture. In fluxing a hard asphalt to any higher penetration, the amount of flux that will be required will therefore depend to a considerable extent upon the percentage of asphaltenes present in the flux. The higher this percentage the more will be required. Owing to the unavoidable variations to which this determination is subject, specification limitations of the percent of bitumen insoluble in naphtha are necessarily wider than tho a definite chemical compound was the solvent used. The determination is useful as a means of identification in some instances, particularly when considered in connection with other tests. Of the solid native bituminous materials, gilsonite shows a high percentage of asphaltenes, usually over 45%, while the bitumen of grahamite appears to be almost entirely composed of asphaltenes. While the test is not generally applied to tars, it is of interest to note that the heavy refined tars are almost entirely insoluble in light paraffin naphthas.

46. Bitumen Insoluble in Carbon Tetrachloride (Carbenes)

Carbon Tetrachloride is a volatile, non-inflammable liquid which is almost as powerful a solvent for bitumen as carbon disulphide. It is a definite chemical compound having the formula CCl_4. In the presence of some organic matter, especially in direct sunlight, it tends to decompose slowly and to liberate hydrochloric acid, altho under ordinary conditions it is chemically stable. With the bitumen which it first dissolves it may later react to precipitate a small amount of insoluble material. This property must be taken into account in its use as a solvent and a short period of digestion is therefore adopted in order to prevent a determination of more insoluble material than is really present.

Method of Determination. The bitumen in petroleum and asphalt products which is insoluble in carbon tetrachloride is known as carbenes. The determination is conducted in the same general manner and with the same apparatus as described in the second paragraph of Art. 44 under THE ORDINARY FILTRATION METHOD for the determination of total bitumen, except that carbon tetrachloride is employed as a solvent instead of carbon disulphide. The percentage of bitumen insoluble in carbon tetrachloride is reported upon the basis of total bitumen taken as 100. The difference between the material insoluble in carbon disulphide and in carbon tetrachloride is the bitumen insoluble in the latter. The method of calculating and reporting results is therefore the same as described in the second paragraph of Art. 45 under the determination of naphtha insoluble bitumen.

Value of the Carbon Tetrachloride Insoluble Bitumen Determination. The presence of carbenes in petroleum and asphalt products is indicative of unnecessarily high temperatures in their production. Most carefully prepared petroleum residuums are as completely soluble in carbon tetrachloride as in carbon disulphide. Incipient cracking due to local overheating or prolonged exposure to high temperatures is indicated by the presence of carbenes altho no coke or organic material insoluble in carbon disulphide may have been formed. Where carbenes in petroleum residuums are accompanied by an appreciable amount of organic matter insoluble in

carbon disulphide, indications point strongly to injury of the material by decomposition of some of the hydrocarbons present. Some native asphalts, such as the Trinidad and Cuban products, are slightly more soluble in carbon tetrachloride than in carbon disulphide, while others that have been produced in nature at relatively high temperatures show appreciable quantities of carbenes. Grahamite in particular may show as high as 60 or 70% of carbenes. With the exception of grahamite, however, the percentage of carbenes in most petroleum and asphalt products for use in highway engineering is commonly specified as less than 0.5%. There is no direct relation which may be expressed between the percentage of carbenes and other physical and chemical properties of a material. Thus, a fluid petroleum residuum carelessly manufactured may contain a relatively large amount, while a solid residuum carefully prepared from the same petroleum may be entirely soluble in carbon tetrachloride. All distillates produced by the fractional distillation of bituminous materials are completely soluble in this solvent. As a rule, tars are not as soluble in carbon tetrachloride as in carbon disulphide, but the difference in solubility appears to bear no relation to the amount of free carbon which is present in the tar. In routine examination of tars carbon tetrachloride is not employed as a solvent and the term carbenes is therefore confined to constituents in petroleum and asphalt products.

47. Fixed Carbon

Method of Determination. The fixed carbon determination is a purely arbitrary test for bituminous materials which has been borrowed from the ordinary methods of coal analysis. In 1911 the Am. Soc. Test. Mat. adopted a "Provisional Method for the Determination of Residual Coke in Bituminous Compounds." This method, as described in somewhat more detail by Hubbard and Reeve (25b) is as follows. The determination is made in accordance with the method recommended in 1899 by the Com. on Coal Analysis, Am. Chem. Soc. (12). The apparatus is illustrated in Fig. 44. One gram of the material is placed in a platinum crucible weighing from 20 to 30 g and having a tightly fitting cover. It is then heated for 7 min over the full flame of a Bunsen burner, as shown in Fig. 44. The crucible should be supported on a platinum triangle with the bottom from 6 to 8 cm above the top of the burner. The flame should be fully 20 cm high when burning freely, and the determination should be made in a place free from drafts. The upper surface of the cover should burn clear, but the under surface should remain covered with carbon, excepting in the case of some of the more fluid bituminous materials, when the under surface of the cover may be quite clean. The crucible is removed to a desiccator and when cool is weighed, after which the cover is removed, and the crucible is placed in an inclined position over the Bunsen burner and ignited until nothing but ash remains. Any carbon deposited on the cover is also burned off. The weight of ash remaining is deducted from the weight of the residue after the first ignition of the sample. This gives the weight of the so-called fixed or residual carbon, which is calculated on a basis of the total weight of the sample, exclusive of mineral matter. If the presence

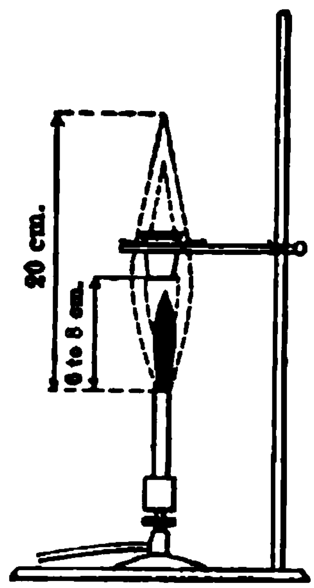

Fig. 44. Apparatus for Determining Fixed Carbon

of a carbonate mineral is suspected, the percentage of mineral matter may be most accurately obtained by treating the ash with a few drops of ammonium carbonate solution, drying at 100° C (212° F), then heating for a few minutes at a dull red heat, cooling and weighing. An excellent form of crucible for this test is shown in the illustration. It has a cover with a flange 4 mm wide, fitting tightly over the outside of the crucible, and weighs complete about 25 g. Owing to sudden expansion in burning some of the more fluid bitumens, it is well to hold the cover down with the end of the tongs until the most volatile products have burned off. This method has been recommended by the Spec. Com. Mat. Road Cons., Am. Soc. C. E. (13) except with regard to the method of heating, which is specified as follows: " The crucible and its contents shall be heated, first gently and then more severely, until no smoke or flame shall issue between the crucible and the lid. It shall then be placed in the full flame of a Bunsen burner for 7 min."

Value of Fixed Carbon Determination. To be of any real value except for the original operator, the fixed carbon determination should be made exactly as described in the preceding paragraph. It is not an exceedingly accurate test and any attempt at variation in the method of heating or other conditions specified will often greatly affect the results obtained. When properly made the fixed carbo test may serve as a means of identifying the type of petroleum from which a fluid or semisolid residuum has been manufactured. Par ffin petroleums and all p:troleum distillates yield little or no fixed carbon. Asphaltic petroleums and their residual products always yield fixed carbon but in varying amounts, according to their origin or method of manufacture. For a given viscosity, float test or penetration, blown petroleums show a very low percentage of fixed carbon, and straight distilled Mexican petroleum residuums an unusually high percentage. For any type of petroleum residuum fixed carbon increases as distillation progresses. It is therefore accompanied by increase in specific gravity, percentage of asphaltenes, viscosity and float test and decrease in penetration. Native asphalts usually yield from 11 to 15% of fixed carbon, altho the harder varieties sometimes run considerably higher, and in the case of grahamite may reach 50% or over. The test is seldom applied to tars or tar products, owing to the presence of free carbon which interferes with the determination. In interpreting the fixed carbon determination it should be remembered that the fixed carbon is actually produced from the material by destructive distillation and does not exist as such in the original material. It is therefore quite distinct from free carbon, which if determined to exist at all is actually present in the original material and is merely separated from the other constituents by means of a solvent.

48. Paraffin Scale

Method of Determination. No very accurate method has as yet been devised for determining the percentage of paraffin scale in petroleum and asphalt products. Most methods require that the material be first destructively distilled and the paraffin scale then recovered from the distillate. Slight variations in method and rate of distillation cause wide variations in results and it appears likely that solid paraffins may be both destroyed and formed under different conditions of distillation. The method as commonly used is as follows. One hundred grams of the material is first weighed into a tared iron retort of about 8 oz capacity. It is then distilled as rapidly as possible without foaming over until only a dry coke residue remains in the retort. The distillate is caught in a 150-cu cm Erlenmeyer flask, the weight

of which has been ascertained. During the early stages of distillation a cold, damp towel wrapped around the stem of the retort will serve to condense the distillate. After high temperatures have been reached, this towel may be removed. When the distillation is completed, the distillate is allowed to cool to room temperature and is then weighed in the flask. This weight minus that of the flask gives the weight of the total distillate. Five grams of the well-mixed distillate are then weighed into a 100-cu cm Erlenmeyer flask and mixed with 25 cu cm of Squibb's ether. Twenty-five cu cm of Squibb's absolute alcohol is then added, after which the flask is packed closely in a freezing mixture of finely crushed ice and salt maintained at -18° C (-0.4° F). After remaining 30 min in this mixture, the solution is quickly filtered thru a No. 575 C. S. & S. 9 cm hardened filter paper placed in a glass funnel, which is packed in a freezing mixture, as shown in Fig. 45. A vacuum should be employed to hasten filtration. The freezing-mixture reservoir shown by *b* may be made by cutting in half a round glass bottle measuring approximately 120 mm in diameter and using the upper half in an inverted position. Any precipitate remaining on the paper should be washed until free from oil with about 50 cu cm of a 1 to 1 mixture of Squibb's ether and absolute alcohol cooled to -18° C (-0.4° F). After the paper has been sucked dry, it should be removed from the funnel and the adhering paraffin scale should be scraped off into a weighed crystallizing dish and dried on a steam bath. The dish and contents should then be cooled in a desiccator and weighed. The weight of the paraffin scale so obtained divided by the weight of the distillate taken and multiplied by the percentage of the total distillate obtained from the original sample equals the percentage of the paraffin scale.

Value of Paraffin Scale Determination. Owing to the fact that the paraffin scale determination is subject to wide variations, it is of doubtful value except as an approximate quantitative test for the purpose of identification. By some the presence of solid paraffins in a bituminous material for use in highway engineering is believed to be undesirable. While it is true that those petroleum products in which paraffin hydrocarbons greatly predominate are unsuited for use as cementing mediums and while a high percentage of liquid paraffin hydrocarbons is often indicated by the presence of an appreciable amount of paraffin scale, it does not follow that the latter are themselves entirely undesirable constituents. In fact, if the material in which they occur possesses the requisite degree of cementitiousness, the presence of solid paraffins may make the material more chemically stable than it otherwise would be.

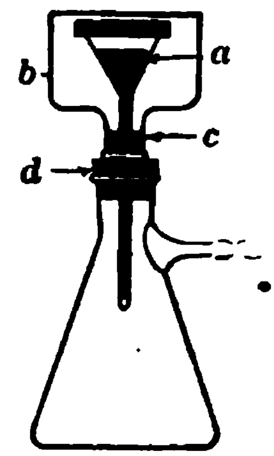

Fig. 45. Apparatus for Determining Paraffin Scale

There appears to be a general tendency to eliminate the paraffin scale clause in specifications for bituminous materials for the reasons above stated. Most asphaltic petroleums and native asphalts contain only traces of paraffin scale while the semiasphaltic type show comparatively small amounts.

SPECIFICATIONS FOR BITUMINOUS MATERIALS

49. Factors Governing Specifications

Value of Tests. Tests of both physical and chemical properties of bituminous materials serve two main purposes: (1) As a matter of investiga-

tion, they constitute a record of the characteristics of the material examined; and (2) when considered in connection with the behavior of a material in use, they serve as a guide for the selection of such material for future use. In the matter of investigation it is often highly desirable that the greatest possible number and variety of tests be applied to a material of construction, as by this means the most complete record of its characteristics is obtained. After considerable data of this sort have been secured on many lots of the same material, it is not as a rule necessary to make use of all of these tests in selecting such material for future use. Certain inherent and peculiar characteristics as determined by tests are, however, of value in the matter of selection, and such characteristics, when governed by quantitative limits, are made the basis of specification for that material. Individual tests as required by specifications for bituminous materials may serve one or more of the three following purposes: (1) They may directly indicate the suitability for a given use of the material specified; (2) they may serve as a means of identifying the source of a material or even the material itself; (3) they may serve to control uniformity in the preparation or manufacture of a material. The first of these purposes is undoubtedly the most important, but it is only partly accomplished by a comparatively few tests. As examples may be mentioned tests of consistency, such as viscosity, the float test, and the penetration test. These tests can only be of maximum value, however, when applied to a specific type of bituminous material and when considered in connection with other tests, which by themselves may not directly indicate suitability. The identification of a bituminous material may be indicated by a number of tests, such as specific gravity, melting point, solubility in carbon disulphide and fixed carbon. The specific gravity determination is perhaps the most important test of identity and this is particularly true when it is considered in connection with the consistency of a material and one or more of the other tests enumerated. Control of uniformity in the preparation or manufacture of bituminous materials is secured by the tests for consistency in connection with melting point, flash point, volatilization, distillation, solubility in paraffin naphtha, and solubility in carbon tetrachloride. Practically all of the other tests may also be made to serve this end. No one by itself will, however, necessarily accomplish this purpose, no matter how close the test limits are drawn. This is mainly due to the fact that products of innumerably varied and complex characteristics may be produced from a given crude material by modifying the method of manufacture.

The Interrelationship of Tests, aside from their individual significance, should be clearly understood for the intelligent interpretation of specifications of bituminous materials, or otherwise the purpose of a specification may be defeated thru conflicting or discriminating clauses which by themselves are apparently above criticism. In all specifications tests are included with at least one and usually two test limits. It is the interrelationship of the limiting factors which is of most importance. The interrelation of any two tests is not a difficult matter to grasp, but when the bearing of three, four, or a dozen tests upon some other has to be considered, the subject becomes complicated and a thoro knowledge of the origin, manufacture and serviceability of the material specified is necessary for an intelligent interpretation of a specification. The prevalent practice of borrowing specifications from other sources, particularly borrowing portions of such specifications and attempting to combine such portions into a single new specification without a knowledge of the interrelationship of tests, is more

than apt to produce a conflict in requirements. This may be illustrated by the following comparatively simple example in which only three factors are considered.

Table XXX.—Comparative Specification Requirements

	A	B	C
Specific gravity 25°/25° C......	0.990–1.010	1.030–1.050	1.030–1.050
Penetration at 25° C, 100 g, 5 sec	50–60	50–60	50–60
Melting point (cube method)....	80° C+	50–60° C	80° C +

It will be noted that the same consistency or penetration requirement is found in all three specifications. Both specifications A and B may be readily met. Thus an asphalt cement of from 50 to 60 penetration may very properly have a specific gravity lying between 0.99 and 1.01 or between 1.03 and 1.05. It may also show a melting point of from 50° to 60° C (122° to 140° F) or not less than 80° C (176° F) as required. If, however, the specific gravity requirement of B and the melting point requirement of A are borrowed to form a new specification C, the combination becomes incompatible from the standpoint of available commercial products. Thus, specification A calls for a blown product while specification B calls for a straight distilled product or one but slightly blown at most. The combination of any two requirements of specification C may readily be met. Two of these combinations exist in the other specifications. The third combination is that of specific gravity and melting point, which if met would greatly lower the penetration limit. From the above it may be seen that as the number of tests to be considered increases their interrelationship may become more and more involved. This subject is further considered in Art. 50.

The Selection of Tests should depend upon the object for which a specification is prepared. A specification should not be encumbered with unnecessary requirements but sufficient requirements should be introduced to insure material which is suitable for the purpose specified and also uniformity of the material. Those tests which are properly specified for bituminous materials most commonly used in highway engineering are as follows:

I. Petroleum and Asphalt Products

1. Specific Gravity of all products.
2. Specific Viscosity of fluids which are too thin for the float test.
3. Float Test of viscous fluids and soft semisolids which are not well adapted for the viscosity or penetration tests.
4. Penetration Test at 25° C, 4° C and 46° C (77°, 39° and 115° F), where possible, for semisolids and solids.
5. Melting Point of the harder semisolids and solids.
6. Flash Point for all products and sometimes the burning point for materials of low flash point.
7. Volatilization Test at 163° C (325° F) of all materials.
8. Consistency of the residues from the volatilization when adapted for the float or penetration test.
9. Total Bitumen in all products.
10. Organic Matter and Inorganic Matter Insoluble in Carbon Disulphide for all products.

11. Bitumen Insoluble or Soluble in 86° B Paraffin Naphtha for all products.

12. Bitumen Insoluble or Soluble in Carbon Tetrachloride for all products.

13. Fixed Carbon for all products.

II. Tar Products

1. Specific Gravity of all products.
2. Specific Viscosity of fluids which are too thin for the float test.
3. Float Test of viscous fluids and semisolids which are not well adapted for a viscosity test.
4. Distillation Test of all products.
5. Melting Point of the pitch residue from distillation test.
6. Dimethyl Sulphate Test in case of mixtures of tar and petroleum or asphalt products.
7. Total Bitumen in all products.
8. Free Carbon or Organic Matter Insoluble in Carbon Disulphide for all products.

In some cases it may be advisable to omit certain of these tests or to include others. In addition to the above it is common practice to insert a clause in specifications for bituminous materials which have to be heated before use that they shall be free from water and shall not foam when heated to a temperature somewhat higher than that at which they are likely to be heated during their use. In specifications for bituminous aggregates the character and grading of the mineral matter are often covered. The selection of test limits involves a consideration of many factors which properly form a part of and are included in other sections. Certain principles in connection with the selection of test limits are, however, given in Art. 50.

50. Illustrative Specifications

Types of Specifications. There are two general types of specifications for bituminous materials: Close or discriminative specifications and open specifications. The latter type may be divided into two classes: blanket specifications and alternate type specifications. Close specifications are designed to secure a given type and grade of bituminous material to the exclusion of all others, whether suitable or unsuitable for the purpose specified. Their use tends to restrict and often absolutely prevents competition. The result is therefore unnecessarily high prices. Blanket specifications are designed to secure unlimited competition by means of covering, in a single specification, all types and grades of material which may be suitable for the purpose specified. In attempting to do this, however, test limits are necessarily stretched to such a point that unsuitable materials are also covered and in any event certainty of uniformity in supply is lost. Alternate type specifications are designed to strike a happy mean between the closed and blanket types of specification. They are in effect a combination of the two. They consist of a number of more or less close specifications for the various types of materials suitable and equivalent in value for the purpose specified, the selection of any particular specification being optional with the bidder. Fair competition is thus secured without sacrificing the prime requisites of suitability and uniformity. Examples of close, alternate type, and blanket specifications, in the order named, are given in the following paragraphs for the purpose of illustrating the principles

involved. Typical specifications for bituminous materials for use in the treatment and construction of the different types of roads and pavements are given in other Sections.

Close Specifications vary greatly in character according to their method of preparation. They may be obviously discriminative by actually naming the type of material required or they may be indirectly discriminative by so fixing test limits that they may only be met by the type of material required, altho that type is not actually named. Discriminative tests and specifications are perfectly proper and often desirable if used in the right way, but their significance should be clearly apparent and they should not be put forward as open specifications. When a given type of bituminous material has a single characteristic property which distinguishes it from other types, test limitations of this property may be so drawn as to make the specification discriminative. The status of such specifications is not usually difficult to ascertain. Thus a specification for a refined asphalt which calls for some 35% of a flesh pink ash as surely indicates Trinidad asphalt as tho the words "Trinidad Asphalt" were included in the specification. Discrimination is, however, sometimes secured by the use of a combination of two or more test limitations, the significance of which is only apparent under the close scrutiny of one who has an intimate and comprehensive knowledge of all types of bituminous materials. Specifications of this class may, as a whole, absolutely eliminate competition, altho no single clause in the specification could be criticized from this standpoint. Some close specifications are less close than others. Thus a specification for an oil asphalt may cover oil asphalt which can be commercially prepared from a number of crude petroleums. It will, however, eliminate native asphalt products and tar products which are equally well adapted for the purpose specified. On the other hand, a properly prepared tar specification will eliminate all petroleum and asphalt products and is therefore a more or less close specification. The following isolated specification serves as an example of the close type, primarily prepared for a fluxed Bermudez asphalt for bituminous macadam construction under certain conditions. It also illustrates an approved form of specifying test limits.

Asphalt Cement Specifications

1. The asphalt cement shall be homogeneous, free from water and shall not foam when heated to 177° C (350° F).

2. It shall show a flash point of not less than 163° C (325° F) when tested in the New York State Board of Health Closed Oil Tester.

3. Its specific gravity, at a temperature of 25° C (77° F) shall be not less than 1.035 nor more than 1.060.

4. When tested with a standard No. 2 needle, by means of a standard penetrometer, it shall show penetrations within the following limits for the conditions stated, the penetrations being expressed in hundredths of a centimenter; 100 g load, 5 sec at 25° C (77° F) from 130 to 160; 200 g load, 1 min at 4° C (39° F), not less than 30.

5. When tested by means of the New York Testing Laboratory Float Apparatus, the float shall not sink in water maintained at 66° C (150° F) in less than 120 sec nor more than 180 sec.

6. When 50 g of the material is maintained at a uniform temperature of 163° C (325° F) for 5 hr in an open cylindrical tin dish 2¼ in in diameter, with vertical sides measuring approximately 1½ in in depth, the loss in weight shall not exceed 3.0% of the original weight of the sample. The penetration of the residue when tested as described in clause 4 with a standard No. 2 needle under a load of 100 g, for 5 sec at 25° C (77° F) shall be not less than one-half the penetration of the original material tested under the same conditions.

7. Its bitumen as determined by its solubility in chemically pure carbon disulphide at room temperature shall be not less than 94.0% nor more than 98.0%.

8. It shall be soluble in chemically pure carbon tetrachloride at room temperature to the extent of not less than 98.5% of its bitumen as determined by clause 7.

9. It shall be soluble in 86° to 88° B paraffin naphtha, of which at least 85.0% distills between 35° and 65° C (95° and 149° F) to the extent of not less than 75.0%, nor more than 85.0% of its bitumen as determined by clause 7.

10. It shall yield not less than 11.0% nor more than 14.0% of fixed carbon.

11. Upon ignition it shall yield not less than 1.0 % nor more than 3% of ash.

From the above it is evident that clauses 3, 4, 5, 6, 9 and 11 eliminate all tar products. The combination of clauses 3 and 4 eliminates blown asphalts, and clauses 7 and 11 eliminate all suitable straight distilled petroleum residuums. Such residuums might of course be doctored up to meet the specification limits but this would hardly be commercially practicable for the existing types of available materials. Following is given, for the purpose of comparison, a typical specification of a refined tar suitable for the same purpose.

Refined Tar Specifications

1. The refined tar shall be homogeneous, free from water, and shall not foam when heated to 121° C (250° F).

2. Its specific gravity at a temperature of 25° C (77° F) shall be not less than 1.150 nor more than 1.200.

3. When tested by means of the New York Testing Laboratory Float Apparatus, the float shall not sink in water maintained at 50° C (122° F) in less than 120 nor more than 150 sec.

4. Its bitumen as determined by its solubility in chemically pure carbon disulphide at room temperature shall be not less than 95.0%, and it shall show not more than 0.2% ash upon ignition of the material insoluble in carbon disulphide.

5. When distilled according to the tentative method recommended by Committee D-4 of the Am. Soc. Test. Mat. in 1911, it shall yield not more than 0.5% distillate at a temperature lower than 170° C (338° F); not more than 12.0% shall distill below 270° C (518° F), and not more than 25.0% shall distill below 300° C (572° F).

6. The total distillate from the test made in accordance with clause 5 shall have a specific gravity at a temperature of 25° C (77° F) of not less than 0.980 nor more than 1.020.

7. The melting point, as determined in water, of the pitch residue remaining after distillation to 300° C (572° F) in accordance with the test described in clause 5 shall be not more than 75° C (167° F).

It will be noted that this specification is entirely different from that for the asphalt cement. The combination of clauses 2, 3 and 4 eliminates all petroleum and asphalt products, and the combination of clauses 3, 4 and 6 practically eliminates all refined coal tars. The specification is therefore close and is limited almost exclusively to refined water-gas tars.

Alternate Type Specifications. While either of the specifications given in the preceding paragraph if used alone would greatly limit competition, it is evident that competition would be considerably increased if the two specifications were made optional and for the work specified the bidder were allowed to furnish material which conformed to either one that he might select. Moreover, after such selection he would be obliged to furnish reasonably uniform material owing to the rather close test limits specified. Unrestricted competition could be secured by using a sufficient number of specifications to cover all of the available types and grades of material suitable for the purpose specified. Thus, a specification for refined coal tar, a specification for a blown petroleum, and two or more specifications for the different types of petroleum residuums could be made alter-

native with the above to the advantage of fair competition but without sacrificing suitability or uniformity. Use of the alternate type specification is growing rapidly and promises to supersede that of the older close specification and the unscientific blanket specification. Numerous examples of alternate type specifications for bituminous materials will be found in those Sections dealing with the different types of bituminous pavements.

Blanket Specifications. The use of a single specification covering all types of bituminous materials suitable for a given purpose would be highly desirable if it could be so drawn as to cover the proper grade of each type without admitting unsuitable grades. The ultimate utilization of tests for the purpose of selecting material suitable for a given use makes it necessary, however, that the test limits adopted shall specifically define the material, and that the material thus defined shall have previously proved satisfactory for that particular use. For some classes of materials these points are not difficult to cover. In the case of bituminous materials, however, the matter is complicated by the numerous varieties or types of bituminous materials in common use, and the overlapping characteristics of various grades of these different types. Standards of more or less established test values have been thrown into question by the introduction of new types of bituminous materials which, while similar to or identical in many respects with other better known materials yet differ from them materially in certain physical or chemical properties. This has made it necessary to either modify old standards or to create new standards to be used specifically for the new materials introduced. The latter method is certainly the safer. The frequent impossibility of covering suitable grades of different types of material by a modification of the standard of one to include the other may be illustrated in connection with the relative consistency of a California oil asphalt and a fluxed Bermudez asphalt suitable for the same purpose. Thus, for a certain type of bituminous concrete pavement under a given set of conditions, the proper penetration limits at 25° C (77° F) for the California asphalt may lie between 70 and 90, while the proper penetration limits for the fluxed Bermudez asphalt to be used in exactly the same type of pavement and under the same conditions may be entirely different, perhaps 140 to 160. It is evident that to attempt to cover the penetration limits of both materials under one specification would be useless. In the first place, such test limits as 70 to 160 are so wide as to insure but little uniformity in different lots of the same material, and in the second place, an entirely unsuitable material of one type might be supplied under the maximum test limit of the other type. A finer distinction may be drawn in the differences between asphalt cements produced by the straight distillation of two types of petroleum, Mexican and California. Thus, high fixed carbon in most asphalt cements produced from Mexican petroleums is a distinguishing characteristic. Relatively low fixed carbon in good asphalt cements produced from California petroleums serve to differentiate them from Mexican products. Here, again, the necessity or desirability of different test limits is apparent, for if the amount of fixed carbon yielded by a California asphalt cement was as high as the 16 or 17% often found in Mexican asphalt cements, indications would point very strongly to injury of the former due to excessive temperatures having been employed in the process of manufacture. With regard to widely different types of bituminous materials, such as tars and asphalts, it is generally admitted that a blanket specification is absolutely unsatisfactory. It is also unsatisfactory to attempt to cover low carbon tars and high carbon

tars under a single blanket specification. In general, however, for any given purpose it is possible to cover suitable grades of all types of available tar products by means of two alternate specifications. Available petroleum products suitable for the same purpose may usually be covered by from two to four alternate specifications and available fluxed native asphalts by two or three alternate specifications. The alternate type plan involves more work, and, until the principles involved are clearly understood, appears to be much more complicated than the blanket specification. As at best the latter is unsafe, if not absolutely worthless, the extra work involved by the former is undoubtedly worth while. Aside from actual suitability of a material, the matter of uniformity of supply is extremely important, as uniform work cannot be secured with material which is not uniform in character. As previously stated, the blanket specification is wholly inadequate to insure uniformity.

PURCHASE, TRANSPORTATION, STORAGE AND INSPECTION OF BITUMINOUS MATERIALS

51. Purchase of Bituminous Materials

Volume Basis. Bituminous materials for use in highway engineering may be purchased upon either a volume or weight basis. Both methods have their advantages and disadvantages. In the last analysis the volume of bitumen purchased and used is of most interest to the highway engineer, but there are certain handicaps to the volumetric method which are sometimes difficult to meet. In the first place, containers are seldom completely filled with bituminous materials and the volumes therefore have to be calculated or estimated. This is not a difficult matter when material is supplied in bulk, as in the case of tank car shipments; but when smaller containers are used, such as barrels and drums, their variation in shape and size may be so great that a determination of the true volume of a given shipment is no simple matter. It is common practice, however, to purchase fluid and soft semisolid materials by the gallon. When this is done the gallon is usually considered at 15.5° C (60° F), and if the material is delivered hot an arbitrary correction for expansion is made as described in Art. 34. This is reasonably satisfactory for materials which are practically pure bitumen, but if it is desired to purchase the material upon a bitumen basis, that is, to pay only for the bitumen delivered, exclusive of all extraneous matter, the volumetric method is not satisfactory as the extraneous matter is not determined by volume but by weight. In comparing prices for bituminous materials, the actual amount of bitumen present in the material is an important factor. It is perfectly evident that gallon for gallon a tar containing 5% free carbon represents more bitumen than one containing 25% free carbon, yet such facts are frequently overlooked.

Weight Basis. The weight basis of purchase is commonly used in connection with the harder semisolid and solid bituminous materials. Weights are of course the same irrespective of temperature changes, and if it is desired to purchase upon the basis of actual weight of bitumen delivered, this may be done by reference to an analysis of the material showing the percentage of bitumen and extraneous material. Asphalts and asphalt cements are thus sometimes purchased and paid for according to the tons of actual bitumen delivered. This is only reasonable as it is evident that a ton of asphalt consisting of practically 100% bitumen will go farther

than a ton of one containing 35% of mineral matter. In other words, 2 tons of the former will be equivalent to about 3 tons of the latter. Carrying this refinement still further, the specific gravity of the pure bitumen should also be considered as a factor in comparing prices, as it is evident that the same weights of bitumens of different specific gravity will represent differences in volume. Such points as these are often neglected altho in a large contract they may often represent considerable monetary value.

52. Transportation and Storage

Tank Cars and Tanks. Fluid bituminous materials ready for use are ordinarily shipped to the consumer in tank cars of from 4000 to 12 000 gal capacity. These tank cars are, as a rule, equipped with steam coils which may be connected from the outside with the boiler of a road roller or tractor in case it is necessary or desirable to heat the material before unloading the tank. Semisolid materials are also sometimes shipped in tank cars, in which case it is very important that the coils be so designed and placed as to insure efficient heating of the entire contents. The older types of steam-heated tank cars are unsuited for the shipment of semisolids but in the most modern types, which are specially designed for the purpose, asphalt cements of very low penetration may be brought to a fluid condition. Tank cars are necessarily subjected to unusual strains and it sometimes happens that leaks will develop in the heating coil. If this occurs and it is necessary to heat the material above 100° C (212° F), serious trouble may result from foaming due to leakage of condensed steam, altho the original material may have been absolutely free from water. For this reason the shipment for long distances in tank cars of semisolid materials which have to be brought to a relatively high temperature before they can be unloaded is not always satisfactory, and the use of tank cars is therefore largely confined to the fluid and rather soft semisolid products which do not have to be highly heated. The tank car method of shipment, while desirable in many ways, is apt to prove expensive unless upon arrival at their destination facilities are at hand for removal of the contents of the tanks within a comparatively short time. It frequently happens that the engineer is not in a position to at once use an entire tank car load of bituminous material upon its arrival. A long spell of rainy weather may, in fact, postpone its use for a number of weeks. This means that the demurrage charges will constitute an appreciable factor in the cost of the material. In addition to the demurrage of $1.00 per day charged by the railroad company, the leasing value of a tank car is stated by Kershaw (26) as being about $1.25 per day. The loss resulting from the detention of a car is considered to fall on the shipper but is actually borne by the consumer, who pays a higher price for the material than would be the case if he were known to have a storage tank available. Kershaw recommends the use of cylindrical storage tanks of about 12 000 gal capacity, measuring approximately 30 ft in length and 8 ft in diameter, set upon steel supports and equipped with steam coils. The tank should be placed so as to give a minimum fall of 2 in in 30 ft toward the outlet, which should be placed as near one end as possible. The arrangement of the steam coils should be such that a coil is placed immediately above or around the opening in the outlet pipe in order to prevent possibility of the outlet becoming blocked by the collection of cold solid material. The main coils should be placed on a cradle as low as possible in the tank, with a maximum distance of ¾ in between the bottom of the coil and the tank. For

the use of heavy materials the outside piping should be steam jacketed. The following cost data is given for the installation of a 12 000 gal storage tank at Greenwich, Conn. This tank was constructed with two compartments, one of which was fitted with steam coils:

Tank, f.o.b. shipping point	$327.96
Freight	52.00
Piping	165.00
Concrete abutments	230.00
Painting	15.00
Extras	5.00
	$794.96

Kershaw further states that " it has not been unusual for towns using from 100 000 to 200 000 gal of oil to pay the railroad company more than $1000 per annum in the form of demurrage, and quotations have been made in favor of the towns equipped with storage, which net a saving of from 2 to 5 mills per gallon."

Barrels and Drums. A very large proportion of the semisolid and solid bituminous materials is shipped to the consumer in barrels or drums. For the harder grades of materials such as refined asphalts, which require fluxing before use, open-head slack barrels are often used. These barrels are clayed on the inside so that, after cutting the hoops, the staves may be stripped from the asphalt with little or no waste. Slack barrels weigh approximately 20 lb and hold from 300 to 400 lb of refined asphalt, depending upon its specific gravity. They are sometimes double-headed, but in storage should always be placed on end. If stored on their sides they are apt to cave in, no matter how hard the asphalt may be, as they are not designed to withstand the unequalized strains produced by the slow flow or deformation of the asphalt from its normal position at the time of filling. Double-head tight barrels of approximately 50 gal capacity but sometimes varying from 40 to 60 gal capacity are largely used for semisolid and viscous bituminous materials. Such barrels may weigh from 60 to 70 lb each and represent approximately 15% of the gross weight of the shipment. They are much stouter than the slack barrels but should be stored on end. Except in the case of fluid products, it is common practice to destroy these barrels when removing their contents, altho the actual value charged for each barrel amounts to two cents or over per gallon of bituminous material. It is sometimes possible to save the barrel with the exception of one head. If this is done wastage thru adhesion of a portion of the material to the inside of the barrel becomes a factor to be considered as well as the loss of time in draining the contents. These losses, together with the return haulage and freight, and the difference in value allowed by the manufacturer for the empty barrel may practically offset the loss of the barrel itself if the hoops are split and the barrel and contents dropt into the melting kettle from which the staves may be removed, as they float to the surface, and used as fuel. Thin sheet metal drums are used to a considerable extent in place of barrels for the transportation of semisolid bituminous materials. These drums are light weight and hold from 375 to 525 lb of material. They are made with both single and double heads. They are considerably cheaper than tight barrels but possess the disadvantage of rusting out upon prolonged storage in the open. They are also readily dented and sometimes punctured during loading and unloading, in which case it is practically impossible to repair them and if not soon emptied the bituminous material gradually leaks out to the level of

the puncture. They cannot well be stacked without being slowly pressed out of shape and bursting. In emptying they are usually cut with a hatchet and the drum and contents thrown together into the melting kettle. When removed from the kettle their ultimate disposal is sometimes a problem to the consumer, as they cannot be destroyed. They possess certain advantages, however, which largely offset their disadvantages. If carefully handled and stored, wastage of the bituminous material is reduced to a minimum as well as cost of transportation. As they have vertical sides there is less loss of floor space during transportation than is the case with barrels.

53. Inspection of Bituminous Materials

Factors Governing Sampling. The proper sampling of bituminous materials is often neglected thru carelessness or lack of appreciation of the factors which should be considered. Too often a single sample is taken at random from a large consignment of material and the analysis of the sample is considered as representing the entire consignment. Such procedure is apt to prove not only valueless but extremely misleading when an attempt is made to correlate the physical and chemical properties of the material with service results. In the first place, all necessary precautions should be taken to insure that the samples shall truly represent the entire lot of material sampled. This can only be done by taking a number of samples from a lot and checking certain characteristics of the individual samples against each other prior to making a complete examination of the mixed samples. Uniformity is one of the most important facts to be ascertained in connection with a shipment of bituminous material and this can never be determined from the examination of a single sample. It is difficult to formulate definite rules which will cover all conditions that have to be met in sampling the various types and grades of bituminous materials used in highway engineering, but the following fundamental principals should always be observed. (1) Take samples with a view to ascertaining the maximum variations in characteristics which the material may possess. (2) Be sure that sample cans are first scrupulously clean and that, in taking samples, no extraneous matter of any sort is introduced. (3) Immediately after filling, the sample cans should be tightly closed and properly marked for identification. (4) Identification marks should be placed on the sample can itself and not upon the lid unless both can and lid are marked. (5) Samples should be packed for shipment in such manner that leakage of contents or contamination by excelsior, paper, or other packing material during transit is entirely prevented. For ordinary analysis samples of not less than 1 pint (approximately 1 lb) should be taken and it is often preferable that they should be twice this size. For fluid products a rectangular can with small screw top is preferable. For very viscous and soft semisolid products a cylindrical can with a tight-fitting pry lid, such as commonly used for paints, will be found convenient. For the harder semisolid and solid products, a shallow rectangular or cylindrical can with ordinary box lid top is suitable. In marking tin cans a 10% solution of silver nitrate will be found useful. The marking should, however, be allowed to thoroly dry before packing or otherwise it is likely to be obliterated. If such solution is not used, the outside of the can should be scraped so as to present a rough surface upon which a gummed label may be securely attached. This is necessary in order to prevent the label from dropping off after the gum has dried. Samples should be taken in the open, preferably during dry weather, but if taken in rainy weather care should be exercised to prevent water from

being introduced into the sample can. Samples should always be examined prior to the use of the material. They may be taken at the point of shipment or upon arrival of the material at its destination. The former practice is preferable as rejection will then incur no loss in handling and transportation.

Sampling from Tanks. Fluid products may readily be sampled from tanks, but with semisolids and solids the matter is more difficult unless the material is first heated to fluid consistency. When a larger order is placed for continuous delivery, as in state highway work, a storage tank may be filled and reserved by the manufacturer for that particular order. The inspector may then be required to sample the entire bulk of material at one time, prior to loading it for shipment. If this is the case, at least three samples should be taken; the tank sealed both at inlet and outlet, and only unloaded in the presence of the inspector. One sample should be taken from the draw-off near the bottom, one from near the top, and one from the center of the tank. A can or bottle attached to a long stick may be used for taking the last named sample. The sampler should have a sufficiently narrow mouth to be closed by a stopper which may be removed by means of a stout piece of twine when it has been dipped to the proper level or the lid of a wide mouth can may be attached to a heavy wire so that it may be removed when desired. When suitable facilities are at hand, it is always well to thoroly agitate the entire contents of the tank prior to sampling. The contents of tank cars may be sampled either at the point of shipment or delivery, in the same manner as described for storage tanks. If the material is sampled at the point of delivery, however, and is a semisolid or solid, it will usually be necessary to first heat it to fluid consistency. This entails considerable expense as the material will either have to be kept hot during the period of test or again heated before use if the results of examination show it to be satisfactory. The necessity of sampling from different levels is apparent when it is considered that a storage tank may contain the residual contents of a number of stills and even a tank car may be partially filled from the last portion of one still and the difference made up from the contents of another still. When sampling from the draw-off of a tank it is always well to discard or return the first two or three gallons removed in order to avoid sampling material which may have remained in the draw-off pipes from a previous filling.

Sampling from Barrels and Drums. When sampling from small containers, such as barrels or drums, it is advisable to take one sample from every 20 packages and fraction of 20 over 10 in a given shipment. The most satisfactory time to sample is when the material is being run from the still or storage tank into the container, as it is then always fluid and the sample may be obtained with an ordinary tin dipper. If the material has already been placed and stored in barrels or drums prior to sampling, it is quite possible that various lots of different grades of material may have become inadvertently mixed thru careless handling. The containers sampled should therefore be carefully selected with reference to their position in the shipment and the manufacturers' markings which they may carry. These markings should be recorded for every container sampled and used as a means of identification. In no case should two adjacent containers be sampled unless they bear different markings. In the case of double-head barrels, it is good practice to occasionally up-end every other barrel selected and sample from what was the bottom. When the material is in drums or slack barrels some samples should be taken, if possible, 5 or 6 in below the surface. This is advisable because, when a con-

tainer is first filled with hot material considerable contraction takes place upon cooling and after cooling, the container may be topped by running in additional material. It is possible that thru mistake the material used for topping may be of a different grade, and samples taken from the tops will therefore not represent the consignment. Samples of solid products may be chipped out with a hatchet. If any water or dirt is on the surface of the material in the barrel or drum selected for sampling, it should be removed so that the surface is clean and dry. A large sponge will be found useful for this purpose. If the material is too soft to be chipped out, a central portion of the top surface, from 5 to 10 in long and 2 to 4 in wide, may be removed to the desired depth by means of a broad stiff putty knife. A hatchet or small hand axe is often convenient to mark out the portion which is to be removed. The first cut is thrown away and the sample taken from the bottom of the hole by means of the putty knife.

Control Inspection of bituminous materials from the engineering standpoint is necessary at the laboratory, paving plant and on the highway. Upon receipt by the laboratory of a number of samples representing a given consignment, tests for consistency should be made upon each sample and a specific gravity determination on every alternate sample. If these tests check within reasonable limits, the samples are mixed and a complete analysis run on the mixed sample to determine whether the material conforms with specifications. After a consignment has been approved for use, the laboratory then serves as a check upon the plant or highway inspection. The plant inspection of bituminous materials has mainly to do with temperature control, consistency control and regulation of the amount of bituminous material used. All melting and fluxing kettles should be provided with stationary thermometers for determining the temperature of the material at all times. When a tank or kettle of material has been maintained at an elevated temperature for a considerable length of time, the inspector should sample the contents and make a consistency test of the sample to determine whether or not undue hardening has occurred. He should be provided with the necessary equipment and a suitable place for making these tests. He should occasionally forward a sample of bituminous material to the laboratory for check and should superintend and record the use and amount of flux required to soften the material if fluxed products are prepared at the plant. If a heated mineral aggregate is used, he should inspect and control the temperature of such aggregate in order to prevent possible injury to the bituminous material thru its overheating. For this purpose he should be provided with a suitable armored thermometer. He should inspect the measurement and proportioning of the bituminous material with reference to its incorporation with the aggregate and should see that the weighing bucket is frequently tared. He should take occasional samples of the bituminous aggregate and forward same to the laboratory for a check upon the percentage of bitumen and grading. In the case of sheet-asphalt surface mixtures he should make temperature and pat tests upon the samples taken, for his own guidance and check as to whether or not the proper percentage of bitumen is being used. Full details of his duties in this connection will be found in Sect. 17. If at any time it is necessary to change from one type of material to another, he should see that the tanks and kettles are first emptied and scrupulously cleaned in order to prevent mixture of the two. The inspector at the highway should inspect the temperature of the bituminous material or bituminous aggregate as delivered for immediate use. He should see that the

bituminous aggregate is laid to proper thickness and that it is properly compressed. He should cut out occasional sections of the wearing course in the case of fine bituminous aggregate pavements and submit same to the laboratory for density determinations. In case there is no stationary paving plant and the bituminous material is handled directly upon or adjacent to the highway, his duties, according to the type of work done, should be similar to those enumerated for the plant inspector.

SECTION 13

DUST PREVENTION BY THE USE OF PALLIATIVES

BY

JOHN R. RABLIN

ENGINEER, METROPOLITAN PARK COMMISSION OF MASSACHUSETTS

GENERAL DATA

1. Causes of Dust

The Causes of Dust Formation on street and road surfaces are chiefly from three sources, the wearing of the materials of which they are composed, the deposition of foreign materials upon them from outside sources by the wind, by the wheels of vehicles and by leakage from vehicles, and the excrements of animals. The degree of dust formation depends upon the amount and kind of traffic, the type of roadway surfacing and climatic conditions. On hard, smooth pavements the formation of dust from wear is not excessive and its presence is principally due to the last two causes. On broken stone, gravel and earth roads dust formation is excessive and occurs from all three causes, but principally from the wearing away of the surfaces by the vehicles passing over them. Also the methods and materials used in construction and the condition in which the roadway surfaces are maintained have an important bearing upon the formation of dust. Conditions which have a tendency to confine traffic to a single track on a roadway surface, such as too narrow construction, too much crown, and loose, soft surfaces, will increase the formation of dust. See (5).

The Effective Means of Suppressing the Dust Nuisance are the prevention as far as possible of the formation of dust, the proper and systematic cleaning of the roadway surfaces and the use of palliatives.

The Determination of the Necessity for and the Advisability of Using Dust Palliatives depends upon the type and condition of the roads, the character and amount of traffic using them, and the local conditions bordering them. The selection of the materials for dust prevention best suited to each case depends upon these same considerations, with the addition of that of cost.

2. Selection of Materials

City Streets, generally constructed with hard, smooth pavements, are subjected to extreme amounts of very heavy traffic. Altho frequent and thoro cleaning is the best dust preventive, the use of palliatives is necessary. The only materials which can be used on such surfaces are water and solutions of calcium chloride. On city streets with water-bound broken stone surfaces, in residential districts, or localities where the traffic is not excessive, calcium chloride, waste sulphite liquors, oil emulsions or light oils may be used. Light tars and medium oils may be used where the street can be closed to traffic for a sufficient length of time to allow for their application and covering with sand or stone screenings. More permanent results are obtained with the last mentioned materials. This class of streets, constructed with bituminous surfaces, if proper attention is given to cleaning, seldom requires the use of palliatives. When dust formation occurs from a worn condition, an application of a light material of the same nature as that with which the surface is constructed will usually be effective for a considerable length of time.

Suburban and Town Streets, constructed with water-bound broken stone and gravel surfaces, are subjected to greatly varying amounts and character of traffic, and in the selection of materials these are the chief considerations. The number of materials from which to choose is greater for this class of roads than for any other, and practically all of them may be used, as each is suitable to some conditions existing thereon. On residential streets, which carry no thru traffic, calcium chloride, waste sulphite liquors, oil emulsions or light oils may be successfully used; on streets carrying a large amount of thru automobile traffic and a small amount of heavy horse-drawn vehicle traffic, the light or medium oils or light tars should be used; on business streets, calcium chloride, waste sulphite liquors, oil emulsions or light oils are preferable, as the difficulty of applying and protecting the medium oils and light tars practically eliminates them. In all cases where salt solutions and emulsions are to be used, a water supply must be readily available. Tars are not suitable for use on gravel surfaces unless the gravel is of a clean, sandy nature with a small percentage of clay. On bituminous surfaces the same methods should be followed as recommended for city streets.

Country Roads are of two classes, improved roads with broken stone or gravel surfaces, and common earth roads roughly graded and shaped up with the native soil. The first class may be considered as hard roads and the second as soft roads. They are generally subjected to varying amounts of mixed traffic. On the hard road surfaces carrying a considerable amount of about equally divided mixed traffic, tars should be used; on hard road surfaces carrying principally automobile traffic, medium oils or light tars are equally satisfactory; on soft earth roads, on account of the fact that they will generally break up during certain seasons of the year, the use of the heavier materials is inadvisable, and the light oils are about the only kind suitable. The use of salt solutions and emulsions on country roads is generally impracticable, because of the difficulty of obtaining a water supply. Bituminous surfaces should be treated as previously described.

Boulevards and Park Highways are usually subjected to only pleasure vehicle traffic, chiefly automobiles. On the shaded wood roads which carry a small amount of this class of traffic, and which are usually constructed with water-bound broken stone or gravel surfaces, good results

may be obtained by the use of calcium chloride, oil emulsions and light oils. Medium oils and light tars are, however, more durable. The heavily traveled boulevards and park highways, generally having bituminous surfaces, either by being so constructed or by development from the original surface by the application of a carpet of heavy bituminous material, seldom show any dust formation, and when it does occur a retreatment with like material as previously described should be made.

MATERIALS AND METHODS OF APPLICATION

3. Water

Value as Dust Palliative. Water has always been considered an effective dust palliative, and previous to the advent of the swiftly moving motor vehicle was about the only material used for this purpose. The motor vehicle traffic has so changed conditions and requirements that water alone is neither effective nor economical for use on many types of road surfaces. It is generally used on the so-called permanent pavements, such as granite block, wood block, brick and sheet-asphalt, both in the process of cleaning and for sprinkling between cleanings to lay the dust. Its use on broken stone, gravel and earth road surfaces does not give satisfactory results. Its effects vary with the temperature and weather conditions and are of short duration in dry, hot weather, when the conditions are worst. It requires frequent applications during each day and it is difficult to regulate its application so as to obtain uniform results. Considering the benefits derived from its use, the cost is excessive. Altho a certain amount of water on a water-bound broken stone or gravel road is beneficial, an excessive amount will cause muddy and slippery conditions and damage to the surface. Where the traffic consists principally of automobiles, the use of water has a tendency to aid the destruction rather than the preservation of the road surface.

Efficiency and Economy of Watering. Whinery (31) states that "The best known and longest used method of making and keeping streets and roads dustless is by sprinkling with water. At the same time it may be said to be the least developed process, as far as scientific study and application are concerned. Accurate and extended observations on the effect of sprinkling roads and streets, the cost of the process, the quantity of water required, the best and most efficient method of applying the water, and other pertinent matters have either not been made or the results have not been published. If any one doubts this, let him attempt to obtain, from the scanty literature relating to the subject, reliable and consistent data on any of these points.

"Municipal engineers seem to have always looked on street sprinkling as an everyday, matter-of-course operation, not worth serious attention and study, and not susceptible of much improvement in efficiency and economy. It is safe to say that no other municipal function or process receives so little intelligent attention and supervision.

"The cost of efficient street sprinkling is difficult to determine satisfactorily from the data available. Where referred to at all in municipal reports, the necessary conditions to enable one to deduce reliable figures of unit cost are usually wanting. These reports indicate that the cost, exclusive of water, ranges from less than 1 cent to 3½ cents per sq yd for the watering season, which usually extends from May 1st to Oct. 15th. The number of square yards sprinkled once is seldom given, and as the number of times sprinkled per day or per season varies greatly in different cities, and on different streets in the same city, and as there are other varying conditions to be taken into account, it is not possible to get at the basic unit cost from the available records. It is practicable, of course, to estimate the theoretical cost very closely, but such estimates are less satisfactory than actual data from experience.

"The statistics available seem to indicate that, exclusive of the cost of the water,

the average cost per square yard per season is about 2 cents. The quantity of water reported as used is as variable as the cost of applying it. The figures vary from 20 to 70 gal per sq yd per season. Probably 45 gal is a fair average, and, at $90 per 1 000 000 gal, the cost for water per square yard per season would be about 0.4 cent, making the average total cost less than 2.5 cents per sq yd per season. In Boston, where the accounts are now kept with care, the quantity of water used in 1909 was less than 25 gal, and the total cost 2.1 cents per sq yd per season. In the suburban City of East Orange, for the same year, these figures were, respectively, 58 gal and 2.82 cents, including the cost of water.

"As to cost, there is good reason to believe that with careful, intelligent, and economical management, including the restriction of the quantity of water used to that actually necessary, it would not much exceed the average cost of the work as now unsatisfactorily done. Ordinarily, at least, it should not exceed 3 cents per sq yd per season, and this figure may be safely used for comparison with other methods."

Marker (24) states that "It is a well-known fact that water is very effective in allaying dust. When properly applied to a stone road it has some value in preserving the surface, by aiding the stone in retaining its cementing properties. Before repeatedly applying water to a road, the surface should be cleaned, and then the complaint will not be made that the water causes a muddy surface. Water is not only used to allay dust on earth, gravel and macadam surfaces, but also to remove the fine dust which accumulates on such surfaces as brick, sheet-asphalt, wood block, etc, between cleanings. In this latter case it may be the most practical means of preventing dust after reasonable care has been taken in cleaning a street. Generally, from an economic point of view, dust prevention by the use of water on gravel and macadam roads is not very satisfactory, when compared with the use of other means of dust prevention. On hot, dry days, it evaporates very rapidly, and hence its effects are of very short duration. Consequently, on such days when the dust is the most annoying, it is almost impossible, at least impracticable, to keep the surface moist by this means. For rural roads the method of preventing dust by watering is entirely impracticable."

Blanchard (10b) states that "One way to satisfactorily prevent dust on pavements, which are subjected to excessive horse-drawn vehicle traffic, consists of removing street refuse by hand sweeping, during the day; mechanical sweeping of the streets at night; and finally flushing with water to cleanse the surface of the pavement. Periodically watering of pavements to lay dust thruout the day is fundamentally wrong, as the fine dust which necessitates sprinkling should have been removed."

The Usual Method of Applying Water to roadway surfaces for the purposes of dust laying is by means of horse-drawn carts equipped with sprinkling devices in two forms, one discharging the water vertically, and the other horizontally. For use on the hard pavements of city streets the vertically discharging sprinkler valves are preferable, as they are more easily manipulated in operation so as to avoid damage to pedestrians, and the action of the water tends to flush the dust to the gutters without damage to these roadway surfaces. The action of this type of valve on water-bound broken stone or gravel surfaces has a destructive effect, and the valves with horizontal discharge should always be used. The carts consist of a cylindrical tank, either of wood or steel, mounted horizontally on a four-wheel running gear. The capacities of these tanks vary from 350 to 1000 gal, and that usually used has a capacity of about 600 gal. Motor-driven sprinkling trucks are also used for this purpose. The cost of a 600-gal horse-drawn sprinkling cart is about $350.

Amount of Water per Square Yard. Essex (15) states "that each water van, 380 gal effective, should distribute 24 loads per day over 6 miles of roadway watered once, namely, 9000 gal to 88 000 super yd of carriageway, or 10 yd to the gal. At that time the writer was getting only 17 vanloads per day, and in consequence advocated the insertion of a new clause in the street watering contract to ensure the distribution of the 9000 gal required daily. The effect of the new clause was to increase the tender prices for cartage by 1s. 6d. (36.5 cents) per day for supervision; but even then there was an actual saving in distribution in 1913 compared with 1910 of 2.56d. (5.2 cents) per 1000 gal, or £193 ($939.13) for the season. The

Warwick sprinkler, a type which has been largely supplied to municipal authorities, is sent out with a variable spread, by which the carman can empty his van in 6, 4½ or 3 min respectively, but it will be noticed that to distribute not more than 0.02 in with the fine spread he would have to travel 3½ miles per hr, with a medium spread 6¼ per miles hr, and with the heavy spread at the impossible rate of 9 miles per hr. It is the indiscriminate use of such vans that gives rise to most of the complaints as to excessive watering of carriageways, and if all water vans were fitted with a time recorder the head of a department could see for himself when the men were emptying their vans too quickly. In his district the writer has altered all sprinklers to empty in not less than 9 min, which gives a rate of travel of 2½ miles per hr."

The Essex Time Recorder. "The objective of this recorder is to satisfy the municipal surveyor, or other person responsible for the proper watering of town streets and roads, that each van has distributed a certain number of loads per day, that those loads have been full vanloads, and that the times of traveling to and fro between standposts and roads to be watered has in no case been excessive owing to the unsuitable position of any standpost. The recorder consists of a card rotated once in 12 hr by a simple clockwork arrangement with a float inside the water van partially rotating a rod on the top of the van, to the end of which is attached a flat spring arm carrying a pencil which records on the cards."

The Cost of laying dust by sprinkling with water varies greatly and depends upon the efficiency with which the work is done, the cost of labor and water, and the frequency of sprinkling necessary for the different types of road surfaces. From records available the cost varies from 2½ to 4 cents per sq yd of roadway surface for the season when this method can be employed in the average climate of the United States. For efficient work on broken stone or gravel roads the higher cost is nearest correct.

Cost Data on Sprinkling Streets with Water in Webb City, Mo. (28). "During the 145 days of the season of 1912, 5758 tanks, or 475 496 cu ft of water were sprinkled upon the 30 425 sq yd of surface covered. As the water was paid for at a flat rate of $35 per month, this cost the city $0.034 per 100 cu ft. The number of tanks sprinkled per day varied from 15 to 57, with an average of 46. This gives an average of 0.128 cu ft per sq yd per day. Of the 145 days in the season sprinkling was done on 126, or 87% of the time. The 19 days lost represent actual time when, from rain or other causes, sprinkling was unnecessary. However on some days the route was only covered two or three times instead of the regular four trips that were usually made.

Itemized Costs per Day

	Total for 145 Days	Per Day
Driver, 110 days at $2, 35 days at $1.75	$281.25	$1.9396
Collector, 4% of $958.65	38.35	0.2645
Medicine for team	1.40	0.0095
Shoes for team at $3 per set	17.08	0.1177
Hay and bedding, hay at $9 per ton, straw at $0.10 per bale in barn	50.40	0.3476
Feed, bran at $1.25, chops at $1.60, oats at $0.45 and $0.60 in barn	94.75	0.6534
Repairs and renewals to harness and sprinkler	61.65	0.4252
Receipt books, 2000	5.50	0.0379
Water, 4⅔ months at $35	163.35	1.1266
Interest on investment, 6% of $350 for 1 year, 6% of $560 for 5 months	35.00	0.2414
Depreciation on sprinkler, cost $350, life 10 years, 3% compound, 8.73% of $350	30.56	0.2108
Depreciation on team and harness, value $560, life 8 years, 3% compound, or 11.25% of $560, for 5 months of year	26.25	0.1810
Total	$805.54	$5.555"

Cost Data on Street Sprinkling in Manchester, N. H. (23). "The sprinkling season began April 14 and extends to Nov. 1, 200 days, but for 30% of that time sprinkling is not found necessary. The average cost to the city, then, for 140 days of actual sprinkling, is $10 500. The capacity of the sprinklers is 600 gal. The average number of loads per sprinkler per day, 30.46; total gallons per day, 274 200; average gallons per sprinkler per day, 18 280; average distance traveled per sprinkler per day, 13.37 miles; average distance sprinkled per day, 9.64 miles; average effectiveness per day per sprinkler, 72%; average waste travel per sprinkler per day, 28%; average cost per mile sprinkled (effective work) $0.518; average cost per mile sprinkled (effective work) should be $0.371; average distance sprinkled per load of 600 gal, 1670 ft, or 2.78 ft per gal."

Efficiency of Electric Street Watering Vehicle (8). "The chassis is a 3½-ton one, and is 18 ft 6 in long and 6 ft 9 in wide. The tank, which is cylindrical in shape, has a capacity of 750 gal, and is fitted with sleeve valve sprinklers. The spray operates at the front of the vehicle, this making it easier of control by the driver, as there is no necessity for him to turn his head to see where the water is going. With fast moving vehicles this arrangement is of the utmost importance. There is no force pump provided, as the pressure of water in the cylindrical tank produces a spray sufficient to water a street 7 yd wide. The electric vehicle is capable of doing the work of six horse vans. The following comparison is based on 5½ days' work per week.

Cost of Electric Vehicle per Week

	£.	s.	d.	
Driver's wages	1	15	0	$8.52
Power, 384 units at 1d. (2 cents)	1	12	0	7.79
Depreciation	2	10	0	12.17
Sundries, insurance, oil, etc	0	6	0	1.46
Water, 84 500 gal	2	2	3	10.26
Total	8	5	3	$40.20

Cost of Six Horse-Drawn Watering Vans per Week

	£.	s.	d.	
Six drivers' wages at 29s. ($7.06)	8	14	0	$42.34
Hire of 6 horses at 27s. ($6.57)	8	2	0	39.42
Water, 173 000 gal	4	6	3	20.99
Total	21	2	3"	$102.75

4. Sea-Water

Physical Properties. Sea-water, on account of the fact that it contains a certain amount of hygroscopic salts, which have a tendency to absorb and retain moisture, has been used for dust laying purposes in some coast cities and towns, but not to any great extent. Hubbard (4) states: "It has long been known that certain salts have so great an affinity for water that they are not only capable of retaining moisture for a long time under conditions which would otherwise produce rapid evaporation, but that they are capable of absorbing water from the atmosphere to a great extent. Some of these salts are so hygroscopic that, in a humid atmosphere, they will often completely dissolve in the water which they have absorbed from the air. Salts of this character are termed deliquescent, and it is to a great extent these hygroscopic and deliquescent salts that have been employed as dust preventives. Their chemical action upon certain rock powders may also increase the formation of binding material to some extent, but they are not primarily employed for this purpose. Their principal use is to keep the road surface in a semi-moist condition for a much longer

period than would be possible by the application of a corresponding amount of water only, and the number of sprinklings necessary is therefore greatly reduced. One of these salts, magnesium chloride, $MgCl_2$, occurs to a considerable extent in sea-water. The effect of its presence in the cheaper grades of table salt may be seen in the tendency by the salt to lump in damp weather. This is due to the absorption of water by the small amount of magnesium chloride which remains even after the salt has been purified. On account of the presence of this substance, sea-water has been tried, in a number of favorably situated localities, for the purpose of laying dust. While the number of sprinklings has been somewhat reduced by this means the results have, as a rule, been far from satisfactory, owing to the presence of an excessive amount of common salt, sodium chloride, which is applied at the same time and which has no hygroscopic properties. In extremely dry weather, a hard salty scale is produced on the road, which is very undesirable, and in wet weather the mud contains so much salt that it is injurious to the varnish and iron work on vehicles. This strong salt mud is also apt to cause soreness around the fetlocks of horses."

The Use of Sea-Water in the process of flushing and cleaning pavements is of some advantage, as a portion of the hygroscopic salt remains after the cleaning, which tends to keep the street surface damp for a longer period. Except at locations close by the sea front with special equipment for pumping, or in cities having a separate salt water service for fire purposes, its use is prohibitive on account of excessive cost of loading and transporting. The methods of application are the same as for water and the costs are practically the same.

5. Calcium Chloride

Calcium chloride is a hygroscopic, deliquescent salt obtained as a by-product principally in the manufacture of washing soda by the ammonia process. It may be obtained in a solid or granulated form or in the form of a concentrated solution. The granulated form is the most convenient and economical for use for dust laying purposes, as it can be applied to the road surface in this form by the dry method, or it can be readily dissolved in water to make solutions of the desired strength. By purchasing it in the form of a solution, unnecessary transportation charges are incurred on account of the large percentage of water, which in the strongest solution amounts to about 60%, whereas in the dry form the moisture contained amounts to about 25%.

The Action of Calcium Chloride on the Road Surface is the same as that of the magnesium chloride in sea-water, as it absorbs moisture from the air and maintains the surface in a damp condition for a longer time than pure, fresh water. It produces a clean, odorless condition, which is very desirable in residential and crowded city streets. It has little, if any, bonding properties for broken stone or gravel surfaces, except in so far as it retains the fine material. For this reason, on roads subjected to excessive automobile traffic, altho it is more effective as a dust layer than water, it does not preserve the surface to a much greater extent. One advantage of the use of calcium chloride, especially in dry form, over water is that it can be used during cold weather when water would freeze. Table I shows the freezing point and average cost of various solutions of calcium chloride.

Table I.—Calcium Chloride

Freezing Point of Solution	Specific Gravity of Solution	Percent Granulated Calcium Chloride in Solution	Pounds Granulated Calcium Chloride per 600 Gal Solution	Cost Cart Load 600 Gal at Plant	Cost Sq Yd 300 Gal Covering 2000 Sq Yd
32° F	1.000	0.0	0	.....	....
30	1.020	3.5	177	$1.42	$0.00036
28	1.037	6.1	318	2.54	0.00064
26	1.054	8.7	457	3.66	0.00092
24	1.068	10.8	578	4.62	0.00116
22	1.081	12.8	693	5.54	0.00139
20	1.092	14.4	787	6.29	0.00157
18	1.103	16.0	884	7.07	0.00177
16	1.114	17.6	981	7.85	0.00196
14	1.123	18.9	1065	8.13	0.00213
12	1.132	20.1	1141	8.52	0.00228
10	1.140	21.3	1218	9.74	0.00244
8	1.148	22.4	1288	10.30	0.00257

4	1.162	24.4	1419	11.35	0.00283
2	1.169	25.3	1483	11.86	0.00296
0	1.175	26.1	1536	12.29	0.00307
−2	1.180	26.8	1584	12.67	0.00317

This material is particularly effective and suitable for use on gravel walks, fair grounds and resorts which are used by large numbers of pedestrians and on private driveways and race courses.

Report of Committee of Judges of the Roads Improvement Association, England, in 1909 and 1910. "We are of the opinion that the results of the tests of calcium chloride applied in granular form by the 'dry' method have shown that it is a very effective dust layer, and, that it is a cheaper and preferable process to that of street watering, which, as now carried out, is undoubtedly very injurious to macadamized roads; that the treatment has the ill effects of causing, during the winter months, an abnormal quantity of sticky mud, a decided tendency to licking up, and a disintegrating action upon the macadam surface."

Application. Calcium chloride is applied to the road surface by either the DRY or WET method and before the application all excessive loose dust should be removed. In the granular form it is shipped in air-tight steel drums containing about 350 lb. When a drum is opened for use the material should be spread as soon as possible, as it will rapidly absorb enough moisture from the air to cause it to fuse and become lumpy. When applied dry it can be spread with shovels or by means of a fertilizer spreader, the latter method being preferable as it can be more evenly distributed. This spreader consists of a trough about 6 ft long mounted on two wheels. The bottom of the trough is perforated, and the size of the openings is regulated by a movable plate controlled by a lever. There is an agitator running the full length of the trough which operates automatically when the apparatus is in motion and prevents the clogging of the openings. For the first application on broken stone or gravel roads about 1 to 1½ lb to the sq yd of surface should be used and for subsequent applications about one half this amount. Each application of the salts should be effective for from 1 to 2 months, depending upon the traffic and weather conditions. In the use of the dry method of application it is advisable that the surface should be in a damp condition, especially if the weather

is hot and dry. It is also necessary to occasionally feed the salt with sprinklings of water in dry weather. The dry method should not be used on hard permanent pavements, as the salt will be washed or swept by traffic into the gutters before it dissolves. When the calcium chloride is applied by the wet method the salt is dissolved in water to the required strength and sprinkled on the road surface with an ordinary watering cart. The solution, as applied, should contain about 1 lb of salt to 1 gal of water and for a first treatment two applications should be made, with an interval of from 1 to 2 weeks between. Subsequent applications should be made as required at intervals of from 3 to 6 weeks, depending upon conditions before mentioned. A heavier application should be made at the center than at the sides of the road. A strong solution may be made or purchased and stored in metal tanks and drawn off into the carts and diluted as required for application. The material can be more rapidly dissolved by employing some form of mechanical agitation or by stirring with a paddle. A good method suggested by Prévost Hubbard is to suspend the salt in a wire net basket near the surface of the water and as the water in contact with the salt soon becomes a concentrated solution which is heavier than the surrounding water, it sinks to the bottom, producing a circulation and allowing fresh water to constantly attack it.

Cost. Calcium chloride can be purchased in the United States at about $13 per ton f. o. b. at points of manufacture. The cost of treating broken-stone and gravel road surfaces with calcium chloride varies from 2 to 4 cents per sq yd for the usual watering season, and the average cost is about 3 cents. The cost is about the same as that of sprinkling with water and the results are much more satisfactory and even.

Cost of Using Calcium Chloride at Watertown, N. Y. (12c). In 1911 calcium chloride was applied dry from a lime spreader. The streets were first swept by hand. The cost of material, including freight and haul, was $2.85 per drum. About 18 700 ft were treated, 20 ft wide, using 100½ drums of calcium chloride at an estimated cost of 1.33 cents per sq yd. On eleven sections treated, average costs per sq yd were: Sweeping, 0.14 cents; hauling and spreading, 0.14 cents; foreman, 0.05 cents. Total cost on 19 sections averaged 1.69 cents per sq yd.

6. Emulsions

Emulsions to be used as dust palliatives usually consist of water with some saponifying agent and an asphaltic or paraffin oil. Tar is sometimes, tho rarely, used. The saponifying agents most commonly used with oils are alkalies such as potash, soda, ammonia, crude carbolic acid and cheap soap solutions. These form a chemical solution which is miscible with the oils, and when spread upon the road surface separates, and the water quickly evaporates, leaving the oil in a thin evenly spread layer. Paraffin oils used for this purpose produce a greasy condition and give only very temporary results, having no binding qualities. Best results are obtained by the use of asphaltic and semi-asphaltic oils, as after a number of applications a considerable amount of asphalt accumulates on the road surface which not only effectively lays the dust, but also serves as a binder for its protection.

Concentrated Emulsions. Oil emulsions in concentrated form may be purchased from the manufacturers and diluted with water in the carts to the desired strength for application, or may be easily and cheaply prepared by the user. Where this type of palliative is to be used to a considerable extent, a mixing plant may be installed at some central location

for the preparation of the emulsion in the concentrated form, from which it is distributed in this form to the various points of use.

Oil for Emulsion. A typical specification for an oil to be used in preparing an emulsion is as follows: Emulsion oil shall be a petroleum, with an asphaltic base, containing not less than 35% of asphalt; it shall be free from sulphurous hydrogen odors; its specific gravity shall be not less than 0.920 at 25° C (77° F); its flash point not lower than 93° C (200° F); soluble in 86° B naphtha to at least 80%; when 20 g are heated in an open vessel at 163° C (325° F) for 5 hr, the loss in weight by volatilization shall not exceed 20%; it shall be soluble in carbon bisulphide to at least 99.5%.

An Approved Method of Preparing an Oil Emulsion which has been used to considerable extent by the City of Boston is to dissolve 25 to 30 lb of cottonseed soap in 100 gal of hot water; to this solution is added 200 gal of the emulsion oil and the mixture is then agitated for about 20 min. The mixing may be done in the tank of an ordinary watering cart and it is then drawn off into a large storage tank. This concentrated emulsion is then transported to the points where it is to be used and further diluted with water to the desired strength for application.

A Typical Specification for Emulsified Oil to be purchased from the manufacturer ready to be diluted with water for application is as follows: The compound must be of an asphaltic petroleum base, showing not less than 35% asphaltic residue, so compounded that it is easily miscible with water in varying proportions of 10 to 50%, and when so mixed with water, it is suitable for application to the road thru the ordinary sprinkling wagons. The emulsion when spread upon the road shall be entirely without odor. The emulsion shall have such drying and penetrating properties that when applied to a broken stone surface under direct sunlight, at a temperature of not less than 10° C (65° F) and 60% of humidity, it will not adhere to vehicle tires or soles of shoes after 5 hr from the time of its application. The compound shall possess the following characteristics: It shall be free of objectionable coal tar products and sulphurous hydrogen odors; specific gravity not lighter than 0.950; flash point not lower than 93° C (200° F); burning point not lower than 149° C (300° F); when heated in an open vessel for 5 hr at 110° C (230° F), the loss shall not exceed 20%; and at 140° C (284° F), the loss shall not exceed 25%. The compound must be entirely soluble in carbon disulphide. It shall not contain more than 1% inert mineral matter.

Application of Emulsions. These emulsified oils are diluted with about three parts of water to one part of oil for first applications, and for subsequent applications may be reduced to four parts water to one of oil if conditions warrant it. The emulsion is generally applied with the ordinary watering cart and a 600-gal cartload should cover an average of 3500 sq yd of roadway surface. The interval between the first and second applications should be from 5 to 7 days, and between the subsequent applications from 1 to 6 weeks, depending upon traffic and weather conditions. The cost of effective dust laying by the use of oil emulsions varies from 2 to 4 cents per sq yd for the usual watering season of 7 or 8 months.

Cost Data, District of Columbia. (12b). In 1910, 190 600 sq yd of broken stone roads were treated with oil emulsions. The following table gives cost and amount of work. On sections 1, 2, and 4, Standard emulsion was used at a cost of 4 cents per gal plus freight. On sections 3, 5, and 6, a product of the Indian Refining Co. was used at a cost of 6 cents per gal.

Section	Sq Yd Oiled	Total Gal	Cost of Labor, etc, Cents per Sq Yd	Cost of Material, Cents per Sq Yd	Number of Applications
1	32 800	8 000	0.553	1.055	6
2	9 800	2 345	0.533	1.041	6
3	72 200	21 545	0.462	1.653	9
4	40 800	10 988	0.669	1.166	12
5	13 500	3 730	0.400	1.651	9
6	15 500	3 450	0.358	1.335	6

7. Light Oils

Oils Used as Dust Palliatives comprise crude petroleums, distillates and fluid residual oils from the distillation of crude petroleum, and cut-back oils prepared by fluxing residuums with distillates. Crude oils are not used to a great extent for this purpose as they are not readily obtainable except in the vicinity of the oil fields where they are produced, and are generally refined to obtain, for other purposes, their more valuable constituents. The California and Mexican crude oils are, however, used to some extent. These oils are known as asphaltic oils and are preferable to the paraffin oils for highway work. Crude paraffin oils are seldom used for purposes of highway work on account of their greasy nature and lack of binding qualities, and also because their constituents are of much greater value for other purposes.

Non-Asphaltic Road Oils for dust laying purposes, several of which are on the market and sold under trade names, are used to some extent in cities and towns. These oils are generally distillates from either asphaltic or paraffin petroleums. They are very light, have no binding properties, and their effects are of short duration, necessitating frequent application. This class of oils has certain advantages over asphaltic oils in that they are cleaner, comparatively odorless and require no covering.

The following Table II by Hubbard (4), shows the differences in properties possessed by three kinds of crude petroleum.

Table II.—Results of Tests of Crude Petroleums

Kind of Oil	Specific Gravity	Flash Point	Volatility at 100° C (212° F) 7 hr	Volatility at 160° C (320° F) 7 hr	Volatility at 205° C (401° F) 7 hr	Residue
Pennsylvania, paraffin	0.801	a	47.3%	58.0%	68.0%	b32.0
Texas, semiasphaltic. .	0.904	43° C (109° F)	20.0%	27.0%	49.0%	c51.0
California, asphaltic. .	0.939	26° C (79° F)			d42.7%	e57.3

a. Ordinary temperature. b. Soft. c. Quick flow. d. Volatility at 200° C (392° F), 7 hr. e. Soft maltha, sticky.

As shown in the Table, the specific gravity increases from the paraffin to the asphaltic oil. This is also true for the percentage of residue, while the volatility decreases correspondingly.

A comparison of the residuums obtained from refining oils similar to those described in Table II is shown in Table III.

Table III.—Results of Tests of Petroleum Residuums

Kind of Oil from which Residuums came	Specific Gravity	Flash Point	Volatility at 200° C (392° F) 7 hr	Residue	Solid Paraffin	Fixed Carbon
Pennsylvania, paraffin	0.920	186° C (367° F)	14.2%	a85.8%	11.0%	3.0%
Texas, semiasphaltic. .	0.974	214° C (417° F)	6.2%	93.8%	1.7%	3.5%
California, asphaltic. .	1.006	191° C (376° F)	17.3%	82.7%	0.0%	6.0%

a. Soft.

In comparing these results, an increase in specific gravities in the same direction as in the case of the crude petroleums will be observed. The

volatility and percentage of residue, however, are not in the same order. As these depend wholly upon the point at which distillation is stopped in the process of refining, such a result is to be expected. In comparing the crude oils with the residuums it will be seen that the latter, as would naturally be supposed, carry a greater percentage of non-volatile constituents, and other things being equal, are therefore of more value as permanent binders.

Fluid Residual Oils obtained from the distillation of crude petroleum are used to a considerable extent in the United States as dust palliatives. Those best suited for the purpose are the residuums from the California, Mexican and some Texas petroleums. The density of these residuums varies considerably from that rich in paraffin hydrocarbons with a specific gravity of about 0.920 to that containing only asphaltic hydrocarbons with a specfic gravity of about 1.000, and the lighter residuums with a specific gravity not exceeding 0.950 are generally used for dust laying purposes.

Cut-Back Oils, which are oils prepared for use as dust palliatives and binders by fluxing heavy residual asphalts with volatile distillates, give very good results. By this method of preparation they can be made of the desired consistency for application and after application the light fluxing material quickly volatilizes, leaving the heavy asphaltic constituents evenly spread on the road surface. Cut-back oils may be obtained having varying specific gravities and asphaltic contents, but usually only the lighter grades are of this type, as these grades are not as readily obtainable in the form of residuals as the heavier grades, on account of the fact that, by the process of refining the crude petroleum to obtain the more valuable products, most of the light constituents are removed.

On broken stone and gravel road surfaces where the traffic is light, a residual or cut-back oil which meets the following specifications may be used with good results and will ordinarily maintain a dustless condition with from two to three applications a year.

Specific gravity at 15.6° C (60° F)	0.920 to 0.950,
Asphalt content at 100 penetration at 25° C (77° F) after evaporation at temperature not exceeding 260° C (500° F)	not less than 45%,
Loss in weight, by heating 20 g 5 hr at a temperature of 163° C (325° F)	not more than 25%,
Bitumen soluble in CS_2 at air temperature	not less than 99.5%,
Bitumen soluble in 76° B naphtha at air temperature	not less than 85%,
Flash point	not less than 54° C (130° F).

On broken stone and gravel road surfaces subjected to a considerable amount of traffic, a large percentage of which is of rubber-tired motor vehicles, excellent results are obtained in the work of laying the dust and of preserving the road surface by the use of oils meeting the following specifications.

Specific gravity at 15.6° C (60° F)	0.940 to 0.970,
Asphalt content at 100 penetration at 25° C (77° F) after evaporation at a temperature not exceeding 260° C (500° F)	not less than 60%,
Loss in weight by heating 20 g 5 hr at a temperature of 163° C (325° F)	not more than 20%,
Bitumen soluble in CS_2 at air temperature	not less than 99.5%,
Bitumen soluble in 76° B naphtha at air temperature	not less than 85%,
Flash point	not less than 54° C (130° F).

Application. Fluid road oils are usually shipped in tank cars of from 6 000 to 10 000 gal capacity. These tanks are generally equipped with steam coils for the purpose of heating the oils if they are of such consistency as to require it for application. In the application of oils having a specific gravity of less than 0.950 and an asphaltic content of 50% or less, heating is not generally required when the air temperature is above 21° C (70° F), but with oils heavier than as above described better results will be obtained by heating before application to about 66° C (150° F). By heating, the heavier oils can be more easily handled and more evenly spread in the desired quantities. Where possible it is advisable to have the tank car set at an elevation above the distributing vehicle so that the oil may be drawn off by gravity. Otherwise it is pumped out either by hand or power pump.

Non-asphaltic and very light asphaltic road oils which are used cold may be applied to the road surface by means of the ordinary water sprinkling cart or gravity distributors, but much better results are obtained by the use of some type of pressure sprayer, even for these light oils. In the application of the heavier grades of road oils, altho the gravity distributor may be used, it is advisable to use pressure sprayers whenever possible. Before applying oils to the road surface it is quite essential that the surface should be cleaned and all loose, fine dust removed, especially when the heavier grades are to be used. The heavier the oil used the more important it is that the surface should be thoroly cleaned. To obtain the best results the oils should be applied as soon as the surface has dried out after a heavy rain or after a thoro wetting with a watering cart, as the fine dust particles are thereby washed from the surfaces of the aggregate and better penetration and adhesion is obtained. At the time of application, however, the surface of the road should be dry and warm. In the treatment of gravel surfaced roads, the washing of the surface is particularly advisable. Before treatment with road oils the surfaces should be put in good repair and all holes and depressions patched and filled. Surface treatments of roads with asphaltic oils as dust palliatives will not provide a new surface for an old worn-out one, but will greatly aid in the preservation and maintenance of a good surface.

The Amount of Oil to be used for each treatment depends upon the condition of the road surface and the kind of oil used. In the use of the lighter oils on a broken stone road surface in good condition, from 1/8 to 1/10 of a gal per sq yd is sufficient, if applied with a pressure sprayer, to lay the dust for from 3 to 6 months. If the road is well worn down to the larger stones, from 1/4 to 1/8 gal per sq yd should be used, and a covering of sand applied. For gravel surfaced roads about the same quantities should be used for similar conditions. If it does not cause too great inconvenience to traffic, it is advisable to close the roadway for a few hours after the application of oil, to allow the oil to penetrate the surface as much as possible before covering with the sand or screenings. One cubic yard of sand or stone screenings will cover an average of 100 sq yd of oiled road surface.

Oiling Earth Roads, according to Piepmeier (26), "will not change their type, and it is folly to expect anything like a permanent road to result from the continued use of oil. Many have thought that after the road had been oiled for a number of years the surface would become saturated and no further oiling would be necessary. Tax payers should be warned against such expectation. The writer has examined a number of streets and roads that have been oiled annually for a period of 10 years and, while it takes a little less oil after the road has been oiled a few years, there is no indication

that such treatments may be eliminated if the desired results are to be expected. There are many earth roads that can be effectively maintained by the intelligent use of oil and the road drag. Besides being graded and drained, the surface should be smooth, free from dust and loose material, vegetation, sod or foreign material of any kind. It should then be rolled with a heavy roller or tractor, or opened to traffic until the entire surface that is to be oiled is uniformly compacted.

"The best time to oil an earth road is soon after a light rain and before the road is rutted. However, the surface should be sufficiently dry to prevent the wheels of the distributer from picking up mud. It is much better to oil on a wet surface than on one which is covered with dust. One of the best oiled roads was treated four times during the summer at the rate of ⅛ gal per sq yd per treatment. When too much oil is applied in one application, it is not only wasted but is often very disagreeable to traffic. When applied in small quantities at different seasons, the oil retains its life, keeps down the dust better, and makes a more waterproof surface. The roads should be sanded after either hot or cold oil has been applied. Clean, hard sand is much better on a road surface than dust or road sweepings. Sand may be applied at a rate of 1 cu yd to each 150 sq yds of road surface. The sand gives an oiled surface more stability. It retains the oil, assists in preventing wear and aids in keeping down the dust. A light application of sand is a justifiable expense on a majority of oiled earth roads.

"A light greasy paraffin oil will lay the dust for a short period but evaporates readily and aids very little in preserving the surface. The light oils that have a natural asphaltic base or a semiasphaltic residue have more lasting qualities, as they more completely fill the pores of the earth surface and readily shed the water and prevent the formation of dust. The best grade of natural asphaltic oils for earth roads will vary from 50 to 65% in asphaltic content, and may ordinarily be applied cold. Some cleaning is generally necessary prior to the first application of oil and this will cost from $25 to $50 per mile. Road oil can be purchased for 3 to 7 cents per gal, depending upon the quality. With average conditions and with a medium priced oil, the average cost of oiling alone per application may be from $200 to $250 per mile of road 15 ft wide."

The Cost of the treatment of road surfaces with oils, varies with the quality and quantity of the oil used and with the varying cost of transportation. Road oils such as are used as dust palliatives, delivered in tank cars thruout the United States, will cost from 3½ to 4½ cents per gal. The cost per sq yd for each treatment for the lighter oils will vary from 1½ to 2½ cents.

Philadelphia Practice. Connell (11b) states that the material generally used consists of asphaltic road oil from 18° to 23° B gravity. "This material is applied to all of the macadam roads that are not in fit condition for the first-class bituminous surface treatment and to all earth roads, and is applied at the rate of 0.2 to 0.25 gal per sq yd. On some roads, depending upon the amount of traffic and whether or not the road is shaded, it is necessary to treat the road in May and treat it again in September. Such roads, however, are the exceptions. In most cases this method of treatment will last for one season. The roads as a rule are not swept before the application, nor is any covering put over this bituminous material, as it is applied in such small quantities that there is scarcely any necessity for covering. The purpose in putting on this small quantity is to insure its disappearing from the road before the winter sets in, in order to avoid the mushy condition that prevails when there is too much oil on the road in this season of the year." Details of cost of using asphaltic road oil, 21° to 23° B, in dust laying in 1915 follow: Square yards treated, 1 167 790; amount per sq yd, 0.23 gal; cost per application, including material per sq yd, 1.1 cents."

Methods and Cost of Oiling in Kansas City, Mo. (27). "Approximately 50 miles of macadam roadways are oiled twice a year by the Park Board of Kansas City. The oil used is a residuum of Kansas oils, which has an average specific gravity of 93 at 15.6° C (60° F). The conditions for oiling are as follows: (1) Before oiling, such repair work as is necessary should be done on the roadway, as the oil forms a cushion over the patch and protects it from raveling; (2) the road surface should be hard and clean and all loose material removed; (3) the road surface should be dry; (4)

only one-half of the roadway should be oiled at a time, if for no other reason than a protection and courtesy to the public; (5) the weather should be warm, with no prospects of rain, as rain on a freshly oiled surface will wash away much of the oil, sometimes completely ruining the job.

The oil is distributed by steel tank wagons, of about 600 gal capacity. To the back of each wagon is attached a sheet iron trough into which the oil is discharged by three 2-in valves, flowing evenly upon the roadway thru small holes in the bottom of the trough. The oil is distributed lightly from the tank wagon upon the roadway, and the tank is immediately followed by the rotary street broom, which spreads the oil over the surface in a thin even coat. Two to four men with hand brooms are necessary to keep oil from running into gutters, and to spread oil on uneven places in the roadway, and at intersections with streets. The oiled surface is then covered with a thin coat of limestone dust, the finest product of the crusher. This is spread from the rear of an ordinary wagon by two men working from the ground with No. 2 scoop shovels.

Detailed Cost of One Application of Oil on Benton Boulevard, Kansas City, Mo.

	55 010 Sq Yd	
	Hr	Per Sq Yd
Foreman, at $2.50 per day	19½	$0.00026
Man, hr on brooms, at $0.25	58½	0.00011
Man, hr spreading dust, at $0.25	89½	0.00040
Man, hr oil wagons, at $0.25	19½	0.00009
Man, hr extra water, etc, at $0.25	28½	0.00011
Team, hr on dust, at $0.50	77	0.00070
Team, hr on broom, at $0.50	21½	0.00019
Team, hr oil wagons, at $0.50	31	0.00029
Cost of delays	......	0.00005
Oil, at $0.025 per gal	3590*	0.00163
Dust, at $0.30 per cu yd	54†	0.00029
		$0.00412"

8. Light Tars

Certain light tars are suitable for use as dust palliatives, under the same general conditions and on the same types of road surfaces as asphaltic oils. These tars are obtained from coal and petroleum in the manufacture of illuminating gas and coke by the process of destructive distillation. They are of two kinds, generally known as coal tars and water-gas tars. The coal tars include gas-house tars and coke-oven tars. Various forms of tars are used in road work, such as crude tars, dehydrated tars, refined tars, cut-back tars and various mixtures of any of these. Only such as may be applied to the road cold are generally considered as dust palliatives, altho some of the lighter forms of those which require heating for application accomplish the same purpose of rendering the road surface dustless, with the added benefits of road preservation. Altho the first cost of the heavier material is slightly more, on account of its greater durability it is often fully as economical in the end and sometimes more so. The advisability of using either the cold application or the hot application materials depends, as with other materials, upon the condition of the surface and the kind and amount of traffic. Generally the heavier grades of tars are unsuited for treatment of gravel surfaced or earth roads, unless

the gravel is particularly clean and free from clay and fine dusty material. They are best suited to the treatment of broken stone road surfaces.

Crude Tars generally give the least satisfactory, and in some cases unsatisfactory results, on account of the presence of water and disagreeable odors, and lack of uniform quality. Dehydrated tars, from which all water, ammonia compounds and some of the light oils have been removed, are sometimes used as dust palliatives with satisfactory results. This form of tar may be obtained of such consistency that it may be used for cold applications. Refined tars are generally considered best for all classes of highway work including dust laying, but most of the refined tars are of such consistency as to require heating for application to the road, and therefore are not considered as dust palliatives. However, as stated before, when used for road treatments, they serve this purpose as well as that of a road binder, for which they are used extensively. Tars which have been refined to the consistency of pitch are sometimes cut back with tar distillates to the desired consistency for dust palliatives. This form of tar, if prepared especially for highway work with proper cut-back material, sometimes gives good results, altho it is not recommended by all authorities. The blending of various tars often produces a grade of tar which is much better for highway work than any one alone. By this method the proportion of the most desirable constituents may be increased and that of the least desirable, decreased so that the resulting product gives excellent results. Some of the commercial products which are on the market are of this form, and are used to a considerable extent.

Specifications for Light Tars. Tars which meet the following specifications are suitable for use as dust palliatives, for cold application:

Specific gravity at 25° C (77° F)	1.05 to 1.18,
Free carbon	2 to 15%,
Viscosity, Engler, 100 cu cm at 60° C (140° F)	not over 125 sec,
Distillation by weight,	
Up to 170° C	not over 5%,
Up to 235° C	not over 18%,
Up to 270° C	not over 30%,
Up to 300° C	not over 40%.

The lighter form of tars which may be used as dust palliatives by the hot application method should meet the following specifications:

Specific gravity at 25° C (77° F)	not less than 1.19,
Free carbon	10 to 25%,
Float test at 100° C (212° F)	18 to 30 sec,
Distillation by weight,	
Up to 170° C	not over 1%,
Up to 235° C	not over 10%,
Up to 270° C	not over 16%,
Up to 300° C	not over 20%.

The Application of Tars to road surfaces as dust palliatives should be by pressure sprayers, as this method is the most effective and economical. In the use of tars it is most essential that the surface shall be thoroly cleaned of all loose or matted dust or dirt. Sweeping is not always effective in removing all dust particles and, as in the use of asphaltic oils, the road surface is in the best condition for the application of tar soon after a heavy rain. It must, however, be dry and warm at the time of application. Whenever tars are used they must be covered with sand or stone screenings before traffic is allowed to go upon them. A period of from 5 to 10 hr should elapse after the application of the material on first treatments before it is covered. On subsequent treatments it may be covered imme-

diately after application. With the cold application of the lighter material from ⅛ to ¼ gal per sq yd is used and one treatment is usually effective for about 1 year.

Cost. The cost of treatments with tars depends upon the grades of tar used and the proximity of the work to the plant where it is produced. Within a distance of from 10 to 15 miles of large cities, where gas plants are usually located, it can be obtained delivered in tank wagons, either horse-drawn or motor-driven, from which it can be directly applied to the road surface. The cost of the light tars at the plant is about 5½ cents per gal. The cost of delivery within a radius of 10 miles of the plant varies from ½ to 1 cent per gal and the cost of application by pressure sprayer is about ½ cent. If it is necessary to ship by tank cars the cost is increased by the freight charges and the expense of handling from the cars to the distributing wagon. The cost of covering with sand or stone screenings varies from 1 to 2 cents per sq yd.

9. Miscellaneous Materials

Patented Compounds made from waste by-products from various industries are used to some extent as dust palliatives. Vegetable oils, animal oils and fats, sulphite liquors and molasses residues have been used in these compounds and have given varying results as temporary dust layers only.

Vegetable Oils, Animal Oils and Fats contain no binding properties, and if used alone act in the same manner as water, merely laying the dust by wetting the particles, but being less volatile than water have a more lasting effect. They are usually combined with an alkali to form a soap to be used for emulsifying mineral oils to form concentrated emulsions. These products are sold under trade names in various sections of the world.

Waste Sulphite Liquor, which is produced from the manufacture of wood pulp by the sulphite process, is a by-product of no value and has been allowed to run to waste in nearby streams. In the crude state it has little binding value, but in concentrated form it exhibits this characteristic to a considerable extent. It is soluble in water and therefore its effects as a binder in road work are rapidly diminished by rains. The addition of small percentages of semiasphaltic oil tends to increase its lasting effect by making it waterproof. Patented preparations of waste sulphite liquor are on the market for use as dust layers and road binders. One of these, sold under the trade name of GLUTRIN, has been used to a considerable extent. It is claimed for this material that it contains the weak acids that are in the sap of the tree and which are capable of dissolving silica or stone; when it is placed on the roadway and comes in contact with the stones, these acids attack that portion of the stones composed of silica, dissolves it and forms, when it becomes dry, a bond which is insoluble in water and proof against changes in temperature. Particularly good results are claimed for this material on roads built of limestone, clayey gravel or red shale. In the use of Glutrin as a dust layer it is applied to the road surface with the ordinary watering carts. It is purchased in concentrated form and is mixed in the proportion of from 25 to 50 gal of the material to about 500 gal of water. It is then sprinkled on the road in such quantities as for ordinary dust laying with water. The treatment is repeated after a few weeks and the interval between each subsequent treatment should increase considerably, as after

two or three applications the road becomes impregnated with the material and a bond is formed which produces a hard surface which will be dustless for a considerable period. The number of treatments required for a season depends to a large extent on traffic conditions. This material in concentrated form costs from 12 to 15 cents per gal f. o. b. destination.

Molasses Residues, which are by-products from the manufacture of sugar, have been used to a limited extent as a dust palliative in localities near the sugar refineries, generally for experimental purposes. Being soluble in water, they are of little value unless waterproofed. Experiments have been made with a mixture of molasses, lime and oil. This molasses residue is of some value for other purposes and it is little used in road work.

SECTION 14

BITUMINOUS SURFACES

BY

ARTHUR H. BLANCHARD

CONSULTING HIGHWAY ENGINEER, NEW YORK CITY

GENERAL DATA

1. Classification

General Description. Bituminous surfaces are used on earth, broken stone and gravel roads, on bituminous and cement-concrete pavements, and to a certain extent on brick and wood block pavements. In this section there will be considered primarily methods of constructing and maintaining bituminous surfaces on broken stone and gravel roads, while bituminous surfaces on earth roads, bituminous macadam pavements, bituminous concrete pavements, asphalt block pavements, cement-concrete pavements, brick and wood block pavements will be treated in the sections devoted to the several types of roadway surfacings.

Distinction Between Treatments with Palliatives, and Bituminous Surfaces. As oils and tars are used in the construction of bituminous surfaces and are likewise referred to in Sect. 13 covering dust prevention by the use of palliatives, the distinction between treatments with palliatives and the construction of bituminous surfaces should be noted. Palliatives are materials which mitigate or abate the dust nuisance, while bituminous surfaces consist of superficial coats of bituminous materials with or without the addition of stone or slag chips, gravel, sand or materials of a similar character. It is evident, therefore, that the reapplication of oils and tars when used as palliatives may result in the formation of bituminous surfaces. Hence, the line of distinction between treatments with palliatives and the construction of bituminous surfaces is not clearly defined. The methods

of construction usually considered under the heading of bituminous surfaces are confined to those methods which ordinarily result in a bituminous surface, efficacious for 6 months to 2 years.

Classification of Bituminous Surfaces. Bituminous surfaces may be considered as divided into two classes. The first class consists of thin superficial coats of bituminous material with or without the addition of such materials as stone chips, fine gravel or sand. When this type of bituminous surface has been under traffic for from 1 to 2 years, the road metal, or other material composing the wearing course, is exposed. The second class consists of coats of bituminous material of appreciable thickness, usually over ½ in, and are formed by the application of one or more treatments of bituminous material with sand, gravel or stone chips added. Surfaces of this class are known as bituminous carpets or blankets. They rarely wear down uniformly to the wearing course and hence usually increase unevenly in thickness by retreatments.

2. Historical Development

Development in Europe. As early as 1871, Francou of Auch, France, actually employed tar as a surface treatment in a few trials. His method was to spread the unheated tar on the surface and then set fire to it in order to harden the surface. Christophle in 1880 used tar on a road at Saint Foy, and in 1888 another experiment was tried with this material at Saint Gaudens by Lavique. In 1896, Girardeau conceived the idea of applying hot tar to a road surface by observing the better results obtained when a cold tar application was acted upon by the heat of the sun. It was not until 1901, however, that systematic experiments were carried out. Such experiments were started by Dr. Guglielminetti at Monte Carlo, Geneva and Nice, using coal tar and brushing the same into the road surface. In 1902 trials were carried out at Champigny by the engineers of the Department of Roads and Bridges of France. In the 1903 report on these trials, the French engineers formulated all of the basic principles of superficial tarring.

Development in the United States. Dust suppression was the main cause of the rapid development of the method of surface treatment. While in Europe it led to superficial tarring, in the United States, the first trials of this method were made with light oils. Oil was used for this purpose in 1894 at Santa Barbara, California. Further trials were made in 1898 and oils were used to a very slight extent in different parts of the country up to 1905. A few similar trials were made in Europe with indifferent success. After 1905 the use of oils as a dust palliative rapidly increased in the United States. As a general rule they were light in character and could be applied cold. Tar was first used for a surface treatment in 1894 in Montclair, N. J. It was not until 1905, however, that tar surface treatments were used again. After 1906, the use of both oil and tar surface treatments increased at a rapid rate.

3. Characteristics

General Considerations. A properly constructed bituminous surface on a broken stone or gravel road is impervious and is easily cleaned. It increases the durability of the road, yields no dust due to abrasion of the roadway surface, and enables the crown to be reduced. The lowering of tractive resistance and the character of foothold will depend upon the kind

and amount of the bituminous material used and the grade of the road. When asphaltic materials are used the noise caused by horse-drawn vehicles is comparable to that characteristic of wood block pavements subjected to the same kind of traffic, while bituminous surfaces constructed with a thin coat of tar give forth more noise; in some cases, comparable to that emanating from the impact of horse-drawn vehicle traffic on sheet-asphalt pavements. It is self-evident that the various types of bituminous surfaces are adaptable to many conditions, hence complete preliminary investigations are requisite before the kind of material and the details of the method of construction are adopted. Bituminous carpets and thin bituminous surfaces are particularly adaptable to passenger motor vehicle traffic, and hence usually will give the maximum return on the investment when the roadway is subjected to this class of traffic.

Limitations of Use of Bituminous Carpets. Dean (27) states that "It has been demonstrated that a tar carpet will carry economically 100 automobiles per day per ft in width of roadway, together with a horse-drawn traffic of 15 vehicles per day per ft in width of roadway. A tar blanket is not suitable and should never be used to sustain heavy horse-drawn traffic, but is suitable and economical in carrying automobile traffic. Failures that have occurred with a heavy asphaltic oil carpet have occurred where the ratio of the number of automobiles to the number of horse-drawn vehicles was not any greater than two to one, and if the horse-drawn vehicles are of the heavy two-horse type, with narrow tires, no amount of automobile traffic appears to be sufficient to counterbalance the destructive effect of 15 heavy horse-drawn vehicles per ft in width per day."

Canadian Experience with Oil Carpets, according to McLean (41), is as follows: "An early tendency in the use of asphaltic oils for dust prevention was to seek a carpet coat of ⅛ to ½ in in thickness, made up of successive layers of oil and stone chips or gravel. It was believed that a heavy bituminous covering might thus be cheaply built up. This process has been found impracticable, however, as a thick covering has a tendency to pit or to roll, forming a wavy, uneven road surface. Practice now tends to the use of such a grade of asphaltic oil as will produce a thin, tough film of asphaltic coating rather than the thicker coat of bitumen and gravel."

Slipperiness of Tar Surfaces. Some objection has been raised in England to superficially tar-coated roads, due to alleged slipperiness. Without doubt much slipperiness is due to a smooth coat of tar, the ideal mosaic surface of tar and stones not being secured. Heavy traffic and late tarring contribute to greasiness of a road with consequent slipperiness, since tar applied late in the year and subjected to heavy traffic works up into an emulsion more readily than tar which was applied at the beginning of the season and has set hard by winter.

A British Report (55) on this subject is as follows: "It appears to be generally agreed that any impervious surface must be somewhat slippery and greasy at times of hoar frost, light rains and general humidity. The general practice is to cleanse the surface as frequently as necessary by either washing or brushing, and to sprinkle sharp sand, fine granite chippings, or other similar material sparingly over it. In many cases where surface tarring is adopted on country roads it is the practice to avoid tarring steep hills."

Effect of Use of Bituminous Materials on Public Health, Fish Life and Vegetation. There is no danger of pollution of fish streams if proper precautions are taken during the treatment of a road and if refined tar is employed. It has been shown that if crude tars, having considerable ammoniacal liquor, are used in a manner which will permit of portions of the tar being washed into the stream, it will result in killing certain kinds of fish, trout being especially susceptible. The opinion has been expressed by many that superficial tarring does not injure vegetation except from the possible prevention of the percolation of water thru the road surface

to the roots of trees. Altho certain horticulturists in France have claimed that tarred dust injures vegetation, proof of this assertion has not been presented.

Report of British Engineers (55) to 3rd Int. Road Cong.: "Hygienically tars and bituminous compounds have the advantage of producing *per se* very little dust or mud, but on the other hand the non-absorbent surface which they afford leaves the organic dust resulting from horse-droppings, vegetable débris, etc, free play in cases where such matter is not frequently flushed off the road surface. Tar has disinfecting and germicidal properties which are hygienically in its favor as a surfacing for roads. Conclusive evidence of any injury to vegetation from roads surfaced with either coal tar, pitch, or asphalte appears wanting. The surface washings from roads surfaced with coal tar may be polluted to an extent which will render them injurious to fish life unless the washings are sufficiently diluted with other water. The injurious character of the pollution is affected by the quality of tar used: The most injurious constituents of the tar being, in order, ammonia and its compounds, light oils, and phenols. Hence tar for use on roads in the neighborhood of fishing waters is required to be as nearly free as is practicable from these bodies. Surface washings from roads coated with a properly prepared or refined coal tar are believed to be absolutely harmless to fish life if diluted with 20 times their volume of other water of unobjectionable quality."

Conclusion Adopted by 3rd Int. Road Cong. "Sufficient information is now available to enable engineers to select and specify bituminous binders which will have no prejudicial effect upon public health, fish life, or vegetation; but which, on the contrary, will conduce to conditions of considerable hygienic advantage."

BITUMINOUS MATERIALS

4. Bituminous Materials

The different kinds of bituminous materials used are asphaltic oils, cut-back asphalts, crude and refined water-gas tars, crude and refined coal-gas tars, combinations of refined tars, and combinations of refined tars and asphalts. There has been noted a growing objection to the use of materials, for the construction of bituminous surfaces, which require from 2 to 6 weeks to set up to such an extent that tracking will not occur. Materials, which have given satisfactory results from this standpoint, are refined coal tars and water-gas tars, cut-back asphalts, and combinations of asphaltic materials and refined tars. Within 24 to 48 hr, thin bituminous surfaces constructed with the foregoing materials, using from ¼ to ½ gal per sq yd and a thin covering of stone chips, have set up so that no tracking is noticeable. For the construction of carpets on broken stone and gravel roads, both asphaltic oils and tars are used.

Report of Advisory Board on Highways, N. Y. State Dept. of Efficiency and Economy (19), on use of fluid petroleum products for surface treatments. "The reasons for condemning these specifications (N. Y. Highway Comm. 1913 specifications for cold oil and hot oil) are based upon knowledge of materials having similar physical and chemical properties and the use of such materials in the manner specified. These reasons are as follows: (1) Oils which meet these specifications require considerable time in which to set up, when used in the manner specified; (2) all petroleum products, while in a fluid state, act to a certain extent as lubricants, when used as specified; (3) it is therefore evident that more or less movement of the road surface will take place under traffic during the setting-up period; (4) the bituminous mats or carpets formed invariably become wavy and full of humps and ruts under heavy traffic; (5) due to the character of the resulting surface further maintenance is rendered difficult and costly; (6) prior to retreatment of roads thus repaired, it is often necessary to remove considerable portions of the bituminous mats with picks and shovels or with scarifiers. The above conclusions are in accordance with the results of our investigations of many miles of highways treated as described under substantially the same specifications."

Sharples 16c) states that "The heavy tars and asphaltic oils are suitable, as surface applications, when the traffic is mainly automobiles, and give excellent results. Such,

at least, has been the experience on the main state highways in New England. When, however, to the automobile traffic is added a considerable amount of steel-tire traffic, the conditions change; and if, as is the case in the centers of towns and in the suburban districts of cities, the steel-tire traffic predominates, heavy bituminous surfaces are often failures. During the first rainy period, the steel-tire traffic and the horses' calks will probably cut up the surface, let the water into it, emulsify the bitumen, and produce a very disagreeable bituminous mud. For such traffic conditions, the thinnest possible treatments will give the best results. This is true of both tars and oils. In choosing the bituminous material for a surface which will have to be renewed often, care must be taken to select a material which will allow the application of repeated layers. On a number of roads the material gave good results on the first treatment, but further treatments added from year to year have produced a rolling and easily moved surface, due to the formation of a thick, plastic blanket."

Sources, Manufacture, Physical and Chemical Properties, Tests, Transportation, Storage and Inspection of Bituminous Materials. See Sect. 12.

5. Specifications for Bituminous Materials

Forms of Specifications for bituminous materials, as follows, were adopted at the first conference of State Highway Testing Engineers and Chemists, held at the U. S. O. P. R. in Feb., 1917, (57b).

" **Specification for Tars for Cold Application.**

" GENERAL. The tar shall be homogeneous.

" PHYSICAL AND CHEMICAL PROPERTIES. It shall meet the following requirements:

1. Specific gravity 25°/25° C (77°/77° F) .... to ....
2. Specific viscosity at *......° C (....° F) .... to ....
3. Total distillate by weight:
   to 170° C (338° F) .... not more than ......%,
   to 235° C (455° F) .... not more than ......%,
   to 270° C (518° F) .... not more than ......%,
   to 300° C (572° F) .... not more than ......%.
   Melting point of residue ......° C (......° F) to ......° C (......° F).
4. Total bitumen, soluble in carbon disulphide, ...% to ......%.

" METHODS OF TESTING. Tests of the physical and chemical properties of the tar shall be made in accordance with the methods described, or referred to, on page ...... of these specifications, Tests Nos. ....

" NOTES. 1. In some instances it may be desirable to insert a specific gravity of distillate requirement after the melting point requirement, in which case the wording should be: Specific gravity of total distillate 25°/25° C (77°/77° F) .... to ....

2. In some instances it may be considered desirable to insert a requirement for solubility in dimethyl sulphate of one or more fractions of the distillate. In such cases insert as follows: Solubility in dimethyl sulphate of distillate from ....° C (....° F) to ....° C (....° F) ......% to ......%."

" **Specification for Refined Tars for Hot Application.**

" GENERAL. The refined tar shall be homogeneous and free from water.

" PHYSICAL AND CHEMICAL PROPERTIES. It shall meet the following requirements:

1. Specific gravity 25°/25° C (77°/77° F) .... to ....
2. Float test at †....° C (....° F) .... sec to........sec.
3. Total distillate by weight:
   to 170° C (338° F) .... not more than ......%,
   to 235° C (455° F) .... not more than ......%,
   to 270° C (518° F) .... not more than ......%,
   to 300° C (572° F) .... not more than ......%.
   Melting point of residue ....° C (....° F) to ....° C (....° F).
4. Total bitumen, soluble in carbon disulphide, ...% to ......%.

---

*It is recommended that the viscosity determination be made at 25° C (77° F) or 40° C (104° F), according to the nature of the product desired.

†It is recommended that the float test be made at 32° C (90° F) or 50° C (122° F), according to the nature of the product desired.

"METHODS OF TESTING. (Same as under Specification for Tars for Cold Application.)

"NOTES. (Same as under Specification for Tars for Cold Application, with the following addition.)

In some instances it may be desirable to specify the specific viscosity of the material at the temperature applied. In such cases insert as follows: Specific viscosity ....° C (....° F) .... to ...."

"Specification for Road Oils for Cold Application.

"GENERAL. The road oil shall be homogeneous and free from water.

"PHYSICAL AND CHEMICAL PROPERTIES. It shall meet the following requirements:

1. Specific gravity 25°/25° C (77°/77° F) .... to ....
2. Flash point .... not less than ....° C (....° F), or *....° C (....° F) to ....° C (....° F).
3. Specific viscosity at ....†° C (....° F) .... to ....
4. Loss at 163° C (325° F), 5 hr, ... not over......%, or *..... to .....%.
   ‡ Float test of residue at 50° C (122° F) .... sec to .... sec.
5. Total bitumen, soluble in carbon disulphide, not less than ......%.
6. Percent of total bitumen insoluble in 86° B naphtha ......% to ......%.

"METHODS OF TESTING. Tests of the physical and chemical properties of the road oil shall be made in accordance with the methods described, or referred to, on page ...... of these specifications, Tests Nos. ....

"NOTES. 1. In some instances it may be considered desirable to include a requirement for loss at 105° C (221° F), in which case the wording should be: Loss at 105° C (221° F), 5 hr, ... not less than ......%.

2. In some instances it may be considered desirable to include a requirement for the percentage of residue of .... penetration, in which case the wording should be: Percentage of residue of .... penetration ......% to ......%.

3. In certain cases the inclusion of all the tests listed or noted may not be desirable, but it is necessary to use certain combinations of the tests in order to secure a material suitable for a specified purpose."

"Specification for Road Oils for Hot Application.

"GENERAL. The road oil shall be homogeneous, free from water, and shall not foam when heated to ....° C (....° F).

"PHYSICAL AND CHEMICAL PROPERTIES. It shall meet the following requirements:

1. Specific gravity 25°/25° C (77°/77° F) .... to ....
2. Flash point .... not less ....° C (....° F) *or .....° C (....° F) to ....° C (....° F).
3. Specific viscosity at 100° C (212° F) .... to ....
4. Float test at ....††° C (....° F) ...... sec to ...... sec.
5. Loss at 163° C (325° F), 5 hr, ... not over ......% *or ....% to ......%.
   Float test of residue at 50° C (122° F) ...... sec to ...... sec (or penetration of residue at 25° C (77° F), 100 g, 5 sec, ... to ....).
6. Total bitumen, soluble in carbon disulphide, not less than ...... %.
7. Percent of total bitumen insoluble in 86° B naphtha ......% to ......%.

"METHODS OF TESTING. (Same as under Specification for Road Oils for Cold Application.)

"NOTES. (Same as Notes 2 and 3 under Specification for Road Oils for Cold Application.)

Specifications. The following specifications are given as guides and illustrations of practice in America and Great Britain. Satisfactory specifications covering bituminous materials for surface treatments must be

---

*In cases where the presence of a volatile or light flux is desired, the second form of the flash point requirement and of the loss at 163° C requirement should be used; in all other cases the first form of requirement is applicable.

†It is recommended that the viscosity determination be made at 25° C (77° F) or 40° C (104° F), according to the nature of the product desired.

‡In case the oil is to be used as a dust layer only, this requirement is to be omitted.

††It is recommended that the float test be made at 32° C (90° F) or 50° C (122° F), according to the nature of the product desired.

based upon such local factors, as method of use, type and condition of roadway surface, climatic conditions, etc, and upon sources of supply and methods of manufacture of the bituminous materials. In order to obtain suitable bituminous materials at the lowest possible cost, it is necessary in some cases, to modify specifications from year to year. Again, developments in the art and science of the testing and use of bituminous materials often call for changes in specifications.

U. S. O. P. R. 1918. Specifications for Tar for Cold Application. "GENERAL. The tar shall be homogeneous.

"PHYSICAL AND CHEMICAL PROPERTIES. It shall meet the following requirements:

1. Specific gravity 25°/25° C (77°/77° F)..................1.100 to 1.140.
2. Specific viscosity at 40° C (104° F)..........................25 to 35.
3. Total distillate by weight:
   - To 170° C (338° F)........................not more than 2.0%,
   - To 270° C (518° F)........................not more than 25.0%,
   - To 300° C (572° F)....................... ......not more than 35.0%.
4. Total bitumen, soluble in carbon bisulphide...............95% to 100%.

"PURPOSE AND USE. This specification provides primarily for a material to be used in the surface treatment of macadam, gravel or shell roads, to form a thin wearing mat or carpet which may be built up by subsequent maintenance treatments of either the same type of material or a heavier product. It may also be used for maintenance of tar macadam or tar concrete pavements. The specification is intended to cover water-gas tar and low carbon coke-oven tar products."

Specifications for Tars to be Applied Cold on Broken Stone and Gravel Roadways, recommended in 1914 by Advisory Board on Highways, N. Y. State Dept. of Efficiency and Economy (19).

"TAR 'A' OPTIONAL WITH TAR 'B.'

1. Tar 'A' (water-gas tar) shall be homogeneous, and free from water.

2. Its specific gravity at a temperature of 25° C (77° F) shall be not less than 1.050 nor more than 1.140.

3. When tested by means of the Engler viscosimeter at 40° C (104° F) the specific viscosity of the first 50 cc passing the orifice of the viscosimeter, shall be not less than 12 nor more than 20.

4. Its bitumen, as determined by its solubility in chemically pure carbon disulphide at room temperature, shall be not less than 97.0%, and it shall show not more than 0.2% ash upon ignition of the material insoluble in carbon disulphide.

5. When distilled according to the tentative method recommended by Com. D-4, Am. Soc. Test. Mat., in 1911, not more than 1.0% shall distill below 170° C (338° F) and not more than 40.0% shall distill below 300° C (572° F).

"TAR 'B' OPTIONAL WITH TAR 'A.'

1. Tar 'B' (coal tar base) shall be homogeneous, and contain not over 2.0% of water.

2. Its specific gravity at a temperature of 25° C (77° F) shall be not less than 1.140 nor more than 1.180.

3. When tested by means of the Engler viscosimeter at 40° C (104° F) the specific viscosity of the first 50 cc passing the orifice of the viscosimeter, shall be not less than 8 nor more than 13.

4. Its bitumen, as determined by its solubility (upon a water-free basis) in chemically pure carbon disulphide at room temperature, shall be not less than 92.0% nor more than 97.0%, and it shall show not more than 0.2% ash upon ignition of the material insoluble in carbon disulphide.

5. When distilled according to the tentative method recommended by Com. D-4, Am. Soc. Test. Mat., in 1911, not more than 5.0% of oil shall distill below 170° C (338° F) and not more than 40.0% shall distill below 300° C (572° F)."

1917 Specifications for Refined Tars for Hot Surface Treatments, Am. Soc. Mun. Imp.

"PREVIOUS SERVICE. The Contractor will be required to show to the satisfaction of the Engineer, that the Company manufacturing the refined tar he proposes to use under a given specification has, for a period of at least 2 years, manufactured refined tar in a thoroly equipped plant; and that refined tar manufactured of bituminous

"REFINED TAR 'A' OPTIONAL WITH REFINED TAR 'B.'

1. Refined tar 'A' (water-gas tar) shall be homogeneous, free from water and shall not foam when heated to 121° C (250° F).

2. Its specific gravity at a temperature of 25° C (77° F) shall be not less than 1.140 nor more than 1.180.

3. When tested by means of the New York Testing Laboratory Float Apparatus, the float shall not sink in water maintained at 50° C (122° F) in less than 50 sec nor more than 110 sec.

4. Its bitumen, as determined by its solubility in chemically pure carbon disulphide at room temperature, shall be not less than 95.0% and it shall show not more than 0.2% ash upon ignition of the material insoluble in carbon disulphide.

5. When distilled according to the tentative method recommended by Com. D-4, Am. Soc. Test. Mat., in 1911, it shall yield no distillate at a temperature lower than 170° C (338° F); not more than 20.0% shall distill below 270° C (518° F), and not more than 30.0% shall distill below 300° C (572° F).

6. The melting point as determined in water by the cube method, of the pitch residue remaining after distillation to 300° C (572° F) in accordance with the test described in Clause 5 shall be not more than 75° C (167° F).

"REFINED TAR 'B' OPTIONAL WITH REFINED TAR 'A.'

1. Refined tar 'B' (coal tar base) shall be homogeneous, free from water, and shall not foam when heated to 121° C (250° F).

2. Its specific gravity at a temperature of 25° C (77° F) shall be not less than 1.170 nor more than 1.220.

3. When tested by means of the New York Testing Laboratory Float Apparatus, the float shall not sink in water maintained at 50° C (122° F) in less than 40 sec nor more than 100 sec.

4. Its bitumen, as determined by its solubility in chemically pure carbon disulphide at room temperature, shall be not less than 85.0% nor more than 95%, and it shall show not more than 0.2% ash upon ignition of the material insoluble in carbon disulphide.

5. When distilled according to the tentative method recommended by Com. D-4, Am. Soc. Test. Mat., in 1911, it shall yield no distillate at a temperature lower than 170° C (338° F); not more than 20.0% shall distill below 270° C (518° F), and not more than 25.0% shall distill below 300° C (572° F).

6. The melting point as determined in water by the cube method, of the pitch residue remaining after distillation to 300° C (582° F) in accordance with the test described in Clause 5 shall be not more than 75° C (167° F)."

British Standard Specification for No. 1 Tar, based on specifications of the Road Board of England and adopted in 1916 by the Engineering Standards Com. of Great Britain.

"GENERAL. This tar is suitable for the surface tarring of roads. (As to the use of this tar for making tar macadam, see Road Board General Directions for Surfacing with Tar Concrete, Sect. 16, Art. 13.)

"HEATING. The tar should be heated to such a temperature that it will reach the road surface in a highly fluid condition. The necessary temperature to attain this end will vary with the mode of application of the tar. The tar should be heated in a heater or boiler specially designed to prevent frothing, which will otherwise inevitably occur if the tar contains even a small percentage of water. The desired temperature will generally be found in practice to be between 104° and 116° C (220° and 240° F) in the heater or boiler.

"SOURCE OF THE TAR. The tar shall be derived wholly from the carbonization of coal except that it may contain not more than 10% of its volume of the tar, or distillates or pitch therefrom, produced in the manufacture of carburetted water-gas.

"SPECIFIC GRAVITY. The specific gravity of the tar at 15° C (59° F) shall be as nearly as possible 1.19, and in no case shall it be lower than 1.16 or higher than 1.22.

"FREEDOM FROM WATER AND AMMONIA. The tar shall be commercially free from water, that is, it shall not contain more than 1% by volume of water or ammoniacal liquor, which water or liquor, if present, shall not contain more ammonia, free or

combined as carbonate or sulphide than corresponds to 5 g of ammonia per gal, or 70 mg per litre, of the tar.

"FRACTIONATION. On distillation in a litre fractionating flask, a distillation flask without special fractionating column, ½ to ⅔ filled, the tar shall yield the proportions by weight of distillates stated below; the temperatures of distillation being read on a thermometer of which the bulb is opposite the side tube of the flask:

Below 170° C (338° F), not more than 1% of distillate, light oils, exclusive of water.

Between 170° and 270° C (338° and 518° F), not less than 16% and not more than 26% of distillate, middle oils.

Between 270° and 300° C (518° and 572° F), not less than 8% and not more than 10% of distillate, heavy oils.

The total distillate between 170° and 300° C (338° and 572° F), shall be not less than 24% and not more than 34%, that is, where the middle oils approach the maximum allowed, the heavy oils should approach the minimum allowed and vice versa.

"NAPHTHALENE. The distillate between 170° and 270° C (338° and 518° F), middle oils, shall remain clear and free from solid matter, crystals of naphthalene, etc, when maintained at a temperature of 30° C (86° F) for ½ hr. This requirement may be waived in the case of tar supplied direct from gas works, but the tar from which the naphthalene has been extracted is preferable to tar containing much naphthalene.

"PHENOLS. The distillate between 170° and 270° C (338° and 518° F), middle oils, shall not yield to caustic soda solution more crude tar acids, phenols, than is equivalent to 3% by volume of the tar.

"FREE CARBON. The tar shall contain not less than 12% and not more than 21% by weight of free carbon. The free carbon is to be determined by the weight of the residue after complete extraction of all matter soluble in benzol or disulphide of carbon. The extraction is best carried out in a Soxhlet or similar apparatus by disulphide of carbon followed by benzol."

British Standard Specification for No. 2 Tar. See note following No. 1 Tar.

"GENERAL. This tar is suitable for making tar macadam, and also may be used for surface tarring in very hot weather when the road crust is exceptionally dry.

"HEATING. For surface tarring, the tar should be heated to such a temperature that it will reach the road surface in a highly fluid condition. The necessary temperature to attain this end will vary with the mode of application of the tar. The desired temperature will be generally found in practice to be between 124° and 138° C (260° and 280° F) in the heater or boiler. The tar should be heated in a heater or boiler specially designed to prevent frothing, which will otherwise inevitably occur if the tar contains even a small percentage of water. For the preparation of tar macadam the tar will not generally need to be heated to so high a temperature as for surface tarring, but the necessary temperature should be determined largely by the sensible heat of the stone treated with the tar, and the mode of application or treatment.

"SOURCE OF THE TAR. The tar shall be derived wholly from the carbonization of coal except that it may contain not more than 25% of its volume of the tar, or distillates or pitch therefrom, produced in the manufacture of carburetted water-gas.

"SPECIFIC GRAVITY. The specific gravity of the tar at 15° C (59° F) shall be as nearly as possible 1.21, and in no case shall it be lower than 1.19 or higher than 1.24.

"FRACTIONATION. On distillation in a litre fractionating flask, a distillation flask without special fractionating column, ½ to ⅔ filled, the tar should yield the proportions by weight of distillates stated below; the temperatures of distillation being read on a thermometer of which the bulb is opposite the side tube of the flask:

Below 170° C (338° F), not more than 1% of distillate, light oils and water, if any.

Between 170° and 270° C (338° and 518° F), not less than 12% and not more than 18% of distillate, middle oils.

Between 270° and 300° C (518° and 572° F), not less than 6% and not more than 10% of distillate, heavy oils.

The total distillate between 170° and 300° C (338° and 572° F) shall not be less than 21% and not more than 26%, that is, where the middle oils approach the maximum allowed the heavy oils should approach the minimum allowed and vice versa.

"NAPHTHALENE. The distillate between 170° and 270° C (338° and 518° F), middle oils, shall remain clear and free from solid matter, crystals of naphthalene, etc, when maintained at a temperature of 25° C (77° F) for ½ hr.

"PHENOLS. The distillate between 170° and 270° C (338° and 518° F), middle oils,

shall not yield to caustic soda solution more crude tar acids, phenols, than is equivalent to 2% by volume of the tar.

"FREE CARBON. The tar shall contain not less than 12% and not more than 22% by weight of free carbon. The free carbon is to be determined by the weight of the residue after complete extraction of all matter soluble in benzol or disulphide of carbon. The extraction is best carried out in a Soxhlet or similar apparatus by disulphide of carbon followed by benzol."

Philadelphia 1917 Specification for Cut-Back Asphalt for Cold Application. "The material shall be a cut-back asphalt prepared in a still by compounding approximately 35% of a distillate with an asphalt meeting the following specifications:

Specific gravity at 25° C (77° F)	Minimum 1.02
Penetration, 100 g for 5 sec at 25° C (77° F)	85 to 100
Volatility, 50 g for 5 hr at 163° C (325° F)	Not more than 8%
Solubility, in CCl_4	Not less than 99%
Ductility, Dow method at 25 °C (77° F)	Not less than 60 cm.

"The distillate shall conform to the following requirements:

Baumé gravity at 15.5° C (60° F)	53 to 60
Specific gravity at 25° C (77° F)	0.76 to 0.73
End point of distillation, test to be made upon 100 cc in a 150 cc Engler flask	177° C (350° F).

"The cut-back asphalt made from a combination of the above two products shall conform to the following tests:

Specific gravity at 25° C (77° F)	Minimum 0.893
Volatility, 20 g for 5 hr at 163° C (325° F)	35% to 40%
Penetration of residue, after volatility	35 to 45
Viscosity, Engler, 50 cc at 25° C (77° F)	275 to 350
Gravity of distillate off below 300° C (572° F),	
Baumé	53 to 60
Specific	0.76 to 0.73."

N. Y. State Highway Comm. 1917 Specification for Oil for Cold Application. "This bituminous material shall have the following characteristics:

1. It shall be free from water.
2. The various hydrocarbons composing it shall be present in a homogeneous solution.
3. It shall have a specific gravity at 25° C (77° F) of not less than 0.93.
4. When evaporated in the open air at a temperature not exceeding 260° C (500° F) until the residue remaining has a penetration, 5 sec, 25° C (77° F), No. 2 needle, 100 g weight, of 10 mm, the amount of residue shall not be less than 50% nor more than 65% of the original oil. At a temperature of 25° C (77° F) such residue shall have a ductility of at least 25 cm, Dow mold.
5. Fifty grams of it upon being maintained at a uniform temperature of 163° C (325° F) for 5 hr, in a cylindrical vessel 5½ cm in diameter by 3½ cm high, shall not lose more than 30% in weight.
6. It shall be soluble in chemically pure carbon disulphide at air temperature to the extent of at least 99.5%.
7. It shall be soluble at air temperature in 76° B paraffine petroleum naphtha distilling between 60° and 89° C (140° and 190° F) to the extent of not less than 80% and not more than 95%.
8. It shall not show more than 10% fixed carbon.
9. It shall show an open flash point of not less than 52° C (125° F).
10. It shall not contain more than 4% paraffine scale."

N. Y. State Highway Comm. 1917 Specification for Oil for Hot Application. "This bituminous material shall have the following characteristics:

1. It shall be free from water.
2. The various hydrocarbons composing it shall be present in a homogeneous solution.
3. It shall have a specific gravity at 25° C (77° F) of not less than 0.96.
4. When evaporated in the open air at a temperature not exceeding 260° C (500° F) until the residue remaining has a penetration, 5 sec, 25° C (77° F), No. 2 needle, 100 g weight, of 10 mm, the amount of such residue shall not be less than 85% nor more

than 95% of the original oil. At a temperature of 25° C (77° F) such residue shall have a ductility of at least 25 cm, Dow mold.

5. Fifty grams of it upon being maintained at a uniform temperature of 163° C (325° F) for 5 hr, in a cylindrical vessel 5½ cm in diameter by 3½ cm high, shall not lose more than 10% in weight.

6. It shall be soluble in chemically pure carbon disulphide at air temperature to the extent of at least 99.5%.

7. It shall be soluble at air temperature in 76° B paraffine petroleum naphtha distilling between 60° and 89° C (140° and 180° F) to the extent of not less than 75% and not more than 90%.

8. It shall show between 6 and 14% of fixed carbon.

9. It shall show an open flash point of not less than 163° C (325° F).

10. It shall not contain more than 4.7% paraffine scale.

11. It shall show a toughness at 0° C (32° F) not less than 20 cm. Toughness is determined by breaking a cylinder of the material 1¼ in in diameter by 1¼ in in height in a Page impact machine. The first drop of the hammer is from a height of 5 cm and each succeeding blow is increased by 5 cm."

N. Y. State Highway Comm. 1917 Specification for Asphaltic Emulsion to be Used Cold in Patching (28b). "The emulsion must be homogeneous. It must mix with water in all proportions. It shall be of such fluidity as to readily flow from bung hole of a barrel. Any material accepted at time of shipment, which should prove to be defective by separation within 30 days after date of delivery, will not be paid for by the Department of Highways, and will remain the property of the contractor except when separation may be caused by freezing.

"When distilled up to a temperature of 204° C (400° F), the total loss shall not exceed 32%. Not over 2% shall be an oil distillate. The residue from the foregoing distillation shall have the following characteristics:

1. It shall have a specific gravity at 25° C (77° F) of not less than 1.01.

2. The penetration shall be between 15 and 25 mm when tested for 5 sec at 25° C (77° F) with a No. 2 needle weighted with 100 g.

3. Its solubility at air temperature in chemically pure carbon disulphide shall be at least 98.5%.

4. The solubility of the bitumen at air temperature in 76° B paraffine petroleum naphtha distilling between 60° and 88° C (140° and 190° F) shall be between 72 and 84%.

5. The bitumen shall show between 10 and 15% fixed carbon.

6. It shall not contain over 1% of ash.

7. It shall not contain more than 2% paraffine scale.

8. It shall have a ductility at 25° C (77° F) of not less than 40 cm, Dow mold."

CONSTRUCTION

6. Mechanical Appliances

The appliances used in the distribution of bituminous materials may be classified as gravity distributors and pressure distributors. As the demand developed for a heavier binder, both for surface treatment and penetration work, machines especially designed for distributing these materials began to appear. The market is supplied with so many different types, that a thoro investigation should be made preceding the purchase of a machine.

The following factors should be given consideration when selecting a distributor: (1) Character and range of work upon which the distributor will be used; (2) present and probable requirements in specifications pertaining to type and details of distributors and the work to be done; (3) different types and grades of bituminous materials which the machine will distribute, and the range in the amount per square yard which can be applied; (4) gravity or pressure distribution, and, if the latter, the range in pressure per square inch; (5) method of controlling uniformity and amount of distribution; (6) accessories of distributors for heating material, recording temperature of bituminous material, amount in tank, and amount of pres

sure, and shutting off bituminous material at end of run; (7) width of distribution and means for modifying same; (8) motive power; (9) width of tires and loads per linear inch of tires when tank is full; (10) ease of operation and repair; (11) structural strength; (12) amount and character of labor required to efficiently operate the distributor; (13) economics, including overhead, operation and maintenance charges.

Gravity Distributors. In this subdivision will be considered pouring cans, tanks with hose attached, and distributing machines.

Pouring Cans. With the use of pouring cans alone it is difficult to secure uniform application of the bituminous material. If the application of the material is immediately followed by vigorous brushing with fiber push brooms, very satisfactory surfaces can be obtained. The use of these methods will result in a high labor cost due to two factors, the high cost of labor, especially in the United States, and the slow progress made. Cans should be used with which may be secured the maximum uniformity of application attainable by this method of distribution.

Reservoir Brooms have been used for superficial treatments to a limited extent in England. The apparatus comprises a kettle in which the material is heated and to which are fitted two lines of flexible hose, each of which is attached to the head of a hand push broom. The tar flows thru the flexible hose into the heads of the brooms and is then swept into the road by the men operating the brooms. One man pulls the tar kettle, two work the brushes behind the kettle and a fourth man supplies the kettle with tar.

Hand-Drawn Gravity Distributors. The advantages of hand-drawn distributors over pouring cans are the more uniform distribution of material, the elimination, to a certain extent, of the personal equation, more rapid work, and the practicability of keeping the bituminous material at a higher and more even temperature. A hand-drawn gravity distributor was introduced in France in 1903.

Tanks with Hose Attached. If a tank from which the bituminous material flows by gravity thru a hose and nozzle onto the road is used, brushing is necessary to secure satisfactory distribution.

Machines with Distributing Apparatus. Watering carts were first used in the United States for distributing the light oils and tars for suppressing the dust. The ordinary spray attachments on the carts were not very satisfactory for distributing this class of material. Attention was then directed to modifying the distributing device, still using the wooden-tank wagon. Practically all of the modifications consisted in substituting for water sprinklers one or more horizontal pipes pierced with small holes. These pipes were attached to the outlet pipe of the tank and were placed parallel to the rear axle at the back of the tank. The pipes were usually about the same length as the gage of the rear wheels. The material flowed thru these pipes in small vertical streams onto the road surface. Hence, in distributing small quantities, the road surface would not be entirely covered with the material. Traffic worked the material around on the road surface so that in the course of time a fairly satisfactory result might be obtained. In some American machines, the material flows from pipes onto a flash board and from the board to the surface of the roadway in the form of a sheet. The general practice in Europe in using machines of this type is to follow the distribution by brushing the material into the road. This is done either by hand brooming or by brooms which are attached directly behind the distributor. The brooms are either of the drag or rotary type. The machines are made to be drawn by hand or by horse.

Pressure Distributors. The various types of distributing machines of this class may be grouped in the following subdivisions: Hand-drawn distributors; pressure tanks to which are attached hose and spraying devices or horizontal distributing apparatus; and machines equipped with mechanical power-pumps between the tank and the distributing apparatus.

Hand-Drawn Pressure Distributors. The European machines of this type have capacities of from 50 to 320 gal. Essentially these machines consist of a tank for holding the material, the tanks being heated by direct fire, a semi-rotary pump with a length of suction hose attached to the tank for the purpose of filling the latter and another pump attached to the tank by which it is possible to generate a pressure between the pump and the nozzle. The material is pumped from the tank thru a length of flexible hose to the outlet end of which is fixed an iron pipe fitted with one or more nozzles. The nozzle is of such a form that the material is thrown in a fine cone-shaped spray. When five or six nozzles are used, they are sometimes so arranged that a 2 ft width of surface can be covered at a time, the nozzles being fixed to a pipe on two small wheels. When one or two nozzles are used the distribution is effected by passing them over the road-surface, the pipe being held up by the men. Both the pump for filling and that for pressure are operated by hand, hence it takes at least two men to operate this type of machine, one to run the pressure pump while the other manipulates the hose. In one type of American machine the heated material is pumped into the distributor and applied to the roadway surface by pressure from a tank of compressed air. In other types, the pressure is obtained from hand or small gasoline pumps. These machines are especially useful in connection with maintenance work.

Pressure Tanks. These machines consist of steel tank wagons equipped with steam coils and with either a flexible hose with a nozzle attached or a system of pipes equipped with nozzles. The tanks are hauled by a steam roller which supplies steam for heating the material in the tank and furnishes the steam for the pressure. The bituminous material is forced out by the pressure of the steam between the material and the top of the tank.

Flexible Hose Apparatus. By an arrangement of the piping system, means are provided at the outlet valve of the tank so that the steam can be admitted to either side of the valve. The hose can be easily and thoroly cleaned out before the distribution of the bituminous material is commenced by simply allowing hot steam to pass thru the same. Several types of nozzles have been tried. The best nozzle is cast in such a form that the material is given a twisting motion just before it leaves the nozzle, resulting in a cone shaped spray. Two men are generally used with this machine besides the man on the roller. One man is at the nozzle end of the hose, and the other clasps the hose about midway of its length, and drags it around as the nozzle man distributes the material.

Pressure Distributors Equipped with Air Compressors. Some American distributors efficiently utilize pressure from air compressors. Steam is delivered to the compressors either from a boiler mounted on a distributor or from a steam roller or tractor. By the passage of steam thru a system of pipes, the bituminous material is heated to the desired temperature. The material is distributed thru either one or two horizontal pipes equipped with nozzles.

Pressure Distributors Equipped with Mechanical Power Pumps. Several pressure machines of this type have been invented in the United

States. The distributing devices of all of these machines are alike in having horizontal pipes fitted with nozzles. The machines differ somewhat in the way the pressure is obtained and applied. Pumps, run by a sprocket-drive attachment on the rear axle, by steam, and by gasoline, are utilized. Horses and steam rollers are used for hauling. Some distributors are mounted on motor trucks.

Am. Soc. Mun. Imp. Specification for Pressure Distributor for Surface Treatments. "The pressure distributor employed shall be so designed and operated as to distribute the refined tar specified uniformly under a pressure of not less than 20 lb nor more than 75 lb per sq in in the amount and between the limits of temperature specified. It shall be supplied with an accurate stationary thermometer in the tank containing the refined tar and with an accurate pressure gage so located as to be easily observed by the Engineer while walking beside the distributor. It shall be so operated that, at the termination of each run, the refined tar will be at once shut off. It shall be so designed that the normal width of application shall be not less than 6 ft and so that it will be possible on either side of the machine to apply widths of not more than 2 ft. The distributor shall be provided with tires of widths dependent upon the following relationship between the pressure per square inch of tire and the diameter of the wheel; for a 2-ft diameter wheel, 500 lb shall be the maximum pressure per lin in of width per wheel, an additional pressure of 30 lb per in being allowed for each additional 3 in in diameter."

Mass. Highway Comm. Equipment by Farrington (30a). "As to equipment, for handling the lighter grades of bituminous materials, one or two distributor carts and a pump for transferring these materials from the tank-cars are required, and there should be a tool-house, also tents for the laborers, unless vans are provided.

"For handling the heaviest grades of oil or tar used for surface work, the following plant is needed: 1 10- or 12-ton steam roller; 1 portable heating boiler, 1 steam pump, 2 steel tank-wagons, 1 pressure distributor, if mounted separately, or 2 if attached to the tank-wagons; 1 or 2 watering carts; 1 2-horse sweeper; 1 portable tool-house, and 2 large tents or vans for laborers.

"As to distrib tors, for handling the road oils or the corresponding grades of tars, a gravity machine may be used with good results, if the bituminous material is broomed after it is applied; but the cost of distribution will be less and the results more satisfactory if a pressure distributor is used. For this work, a distributor cart with a pump mounted on a frame back of the tank and connected by chain with a large sprocket bolted to one of the rear wheels is most satisfactory. Under favorable conditions, good results have been obtained with gravity m chines in distributing even the heaviest grades of bituminous materials for surface work; but the chances of failure, if the conditions are not favorable, are such that they should always be applied by pressure distributors if possible. The distributor just described, or one with a gas-engine pump mounted either on the tank-wagon or on separate gear, may be used, but one operated by steam will give the best results. One advantage of the steam distributor is the possibility of cleaning out the pipes and nozzles by blowing steam thru them. Of the steam distributors, there seems to be little choice between the one using the direct pressure of steam in the tank for distributing and the pump type, each having its advantages."

7. Methods of Construction

Preparation of Surface of Wearing Course. Before constructing a bituminous surface on a broken stone or gravel road, every precaution should be taken to secure the best sub-drainage which is practicable under the local conditions. All depressions, pot-holes, ruts, or other irregularities should be filled with thoroly compacted bituminous-coated stone so that the whole surface of the roadway is even. All surplus dust must be removed so that the larger pieces of broken stone of the roadway surface are exposed but without breaking the bond. This cleaning process is accomplished by the use of horse sweepers and fine bass brooms, with coarse fiber brooms and fine bass brooms, or by a vacuum process. If there is caked mud on the surface of the roadway, wet brushing will prove advantageous.

If a bituminous surface is to be constructed on a new broken stone or gravel road, or on one which has just been resurfaced, the bituminous material should not be applied until the crust has had time to consolidate under the action of traffic and with the aid of the binding action of dust and moisture. The length of the period which should elapse before the application of the bituminous material depends upon the kind and amount of traffic, the character of the crust, and the time of the year when the roadway is completed. For example, this period must usually be short, if the roadway is composed of trap rock, is completed in August and is subjected to a traffic of more than 300 high-speed motor vehicles per day; otherwise the roadway will ravel due to the particles of the crust not being thoroly bound together, dry climatic conditions and the disintegrating effects of the traffic. If, on the other hand, the roadway of a residential street was constructed of trap rock in June, and was subjected to local traffic, treatment with a bituminous material probably could be postponed for 1 year. If it is impracticable to postpone the surface treatment, special care should be taken to secure a maximum consolidation of the crust of the roadway by puddling and rolling.

Effect of Size of Road Metal of Wearing Course. It is apparent that the character of the cleaned surface will be affected by the method which was used in the original construction of the roadway. If the practice of French engineers in using large-size stone varying from 1 to 2½ in in longest dimensions for the top course of a broken stone road is followed, and the stone is hard and tough, the desired surface can be easily secured. The surfaces of the large stones in such a roadway are easily cleaned by brushing without the dislodgment of stones in the surface. A clean mosaic surface is of the utmost importance from the standpoint of the formation of a satisfactory bond between the broken stone and the bituminous material. The maintenance of bituminous surfaces on wearing courses of large broken stone is economical, since after the bituminous surface wears away in spots, the mechanically interlocked large stones will of themselves generally have sufficient stability to withstand the effects of traffic until retreated.

On the other hand, if the top course of a broken stone road has been constructed of a product varying in size from ¼ to 1¼-in material, it will be very difficult, if not impossible, in the case of soft stone, to secure an even, clean surface. Even after thoro brushing, a film of impalpable dust usually covers the surface of the roadway. During hard brushing small depressions will probably be formed by the displacement of pockets of dust and the smaller sizes of stone. Furthermore, the wheels of vehicles may adhere to the bituminous material and thus tear up the small mineral matter adhering to it. As soon as the bituminous surface wears out in spots, rapid disintegration of the exposed broken stone or gravel surface, with the consequent formation of pot-holes, is apt to occur.

Dry and Damp Roadway Surfaces. When the bituminous material is applied the roadway surface should be bone dry. If the surface is damp it will be difficult to secure a good bond. If the surface is slightly damp when asphaltic oils or tars are applied without being heated, some engineers believe that better results may ensue because, in their opinion, a more even distribution and adhesion of the material are obtained than when the surface is dry.

Richardson (16c) offers the following explanation in support of the contention that oil adheres better to the surface of a watered macadam road than to a dry road. "There is always a slight coating of dust adhering to the surface stone, which pre-

vents adhesion. If, however, the surface is sprinkled before the application of the oil, it converts this dust into a paste. The dust is the detritus of the rock, and, like clay, it is more or less colloidal. The result is that the dust in this condition will emulsify with the oil when the latter is applied to the surface and will mix with it so readily that the bitumen will come in contact with the rock, and, after the evaporation of the water, will adhere perfectly. Clay and water will mix with any kind of asphaltic oil, and with the greatest facility. A great deal of it has been used on roads in Germany for distributing oil as an emulsion. The clay and water are mixed with the oil, put into the watering-cart, and sprayed on the road."

Conclusion, Am. Soc. C. E. Spec. Com. Mat. Road Cons. (16f). "The success of surface applications is proportionate to the adhesion obtained by the bituminous material to the old roadway surface, and such degree of cleanliness of the latter must be had, by means of sweeping or other methods, as will insure a proper degree of adhesion. The roadway surface should be dry when the bituminous material is applied."

Methods of Application of Bituminous Materials. Distribution of the bituminous material is accomplished by two methods. Flow by gravity is utilized in one method and mechanical pressure in the other. The use of gravity distributors has not been developed to its fullest extent in America, in that the use of mechanical brushes or the brushing of the material into the road by hand brooming has never been adopted extensively. By brushing after gravity distribution, it is possible to distribute uniformly 1/4 to 1/5 gal per sq yd of many of the bituminous materials used for the construction of bituminous surfaces. In some cases, when the distribution is accomplished by hand brooming, the adhesion of the material to the road metal is as good as when the material is applied under pressure. The advantages claimed for pressure distributors are: Aid in cleaning the surface of the roadway, even application, distribution of small amounts per square yard, satisfactory adhesion obtained between the bituminous material and the surface of a clean, dry roadway, and rapid and economical distribution.

Conclusion, Am. Soc. C. E. Spec. Com. Mat. Road Cons. (16g). "The bituminous material, in all cases, should be applied by a pressure distributor designed so that the material will be spread uniformly and with a pressure of not less than 20 or more than 75 lb per sq in."

Fulweiler (16c) has presented the following discussion relative to pressure distribution: "If a heavy pressure is used, it will apparently atomize the bituminous material, and when this happens, it ceases to strike the road with that necessary, directional velocity which blows the dust away as the material is distributed. The nozzles of the machine with which the speaker is most familiar are similar to the flat top Bray burners used for illuminating gas. As they leave this nozzle the two streams of material impinge on each other and form a flat sheet or spray of material at right angles to the original plane of the two streams. The amount of pressure used modifies the shape of the spray. As the pressure is increased the sheet of material strikes the road with increasing force, and blows the dust from the surface very effectively. If the pressure is increased still further, a point will be reached that will cause the lower edges of the spray to open or separate, and at this point the material has become atomized. From this point a further increase in pressure will more completely atomize the material until finally it is all in that condition as it leaves the nozzle and reaches the road in minute drops rather than a solid sheet, actually defeating the desired scrubbing action on the surface."

Crosby (16c) states that "The adhesion of a bituminous material to a stone or concrete surface may be increased by the use of a pressure distributor. The pressure machine seems to act like the cement gun when used on dirty steel, because the sand blown thru the gun against the steel cleans off the dirt and allows a good adhesion of the cement. In the same way, the pressure distributor seems to obliterate the dust film, between the stone or concrete and the pitch, which nullifies the adhesiveness of the latter; at least, where it has often been difficult to obtain adhesiveness under a gravity application, the results have been entirely satisfactory where the same materials have been applied under pressure."

Amount of Bituminous Material. As a general rule from ¼ to ½ gal per sq yd is used for the first treatment, preferably in two applications. The amount applied per treatment depends upon the kind of bituminous material, the character and condition of the surface, and the details of the method of application. For example: A smooth surface composed of large sized, tough, hard stone and well compacted by traffic, would require from 0.25 to 0.35 gal; for a somewhat rough surface of stone having a medium toughness and hardness and recently resurfaced, it would be necessary to use from 0.35 to 0.5 gal per sq yd to form a satisfactory thin bituminous surface.

Penn. State Highway Dept. Practice by Biles (17). "The following is intended as a guide for the amount to be used under various conditions: If the surface of the road is made up of pieces of ballast size stone (2 to 3-in) from which traffic has removed all the fine material, leaving large surface voids between the stones, enough of the bituminous material must be applied so that it will flush up level to the top of the large pieces of stone and firmly bind in the chips and gravel which will lay in the crevices between the stones. If, on the other hand, the surface of the road is equally clean, but traffic has not removed the fine particles between these stones to the same extent and the crevices between them are consequently smaller, then a somewhat smaller amount of bituminous material should be used, since an excess will again flow off the road. In treating a road which has recently been resurfaced, it will be found often that even after all the screenings and fine materials have been swept from the top of the road leaving the large stones bare, there will still be a certain amount of dust and fine material between the stones which had not yet been compacted thoroly by traffic and which will absorb the bituminous material like a blotter, leaving only a brown stain in these spaces. In such cases, the amount of application must be increased until this fine material is well saturated and there is enough of the bituminous material near the surface of the road to bind thoroly the covering of the chips or pea gravel."

Fulweiler (16c) states that "When the steel-tire traffic becomes pronounced on a road or street, the thinnest possible surface treatment seems to give the best results. If it is attempted to apply a cold material with a gravity distributor, it is very difficult to put on much less than ½ gal per sq yd. If a pressure distributor is used, a very much smaller quantity can be applied. If a total of about ⅜ gal per sq yd is put on in three separate applications, the result is apparently quite as desirable as with the single application of ½ gal with the gravity sprinkler, and it is much more uniform. In this way, if a spot is missed on the first application, the second treatment covers it, or if it is missed on the second treatment, the third treatment covers it. By applying three coats and by allowing 8 or 10 hr for each coat to set, the best results are obtained, and ⅛ gal per sq yd is saved. It does not cost any more to apply the material in this way; it simply means that the distributor is driven over a greater distance, and the actual time consumed in applying the material is not the important factor. The time is lost mainly in loading the distributor, hauling it to the road, and getting it ready for work."

Application of Top Dressing. The superficial coat of bituminous material is usually covered with either coarse sand, fine gravel, or stone chips varying from ⅛ to ½ in in longest dimensions. Material containing clay should not be used as disintegration may result by the emulsifying of the clay and water on the bituminous surface. The amount of sand, stone chips, or gravel used per square yard depends upon the quantity and kind of the bituminous material, and the character of the surface of the roadway. From 5 to 22 lb per sq yd have been used satisfactorily for thin bituminous surfaces: 5 to 12 lb for from 0.1 to 0.25 gal per sq yd of bituminous material; 10 to 17 lb for 0.25 to 0.35 gal; and 15 to 22 lb for from 0.35 to 0.5 gal.

Top dressing is distributed by hand and machine methods. In the machines employed for this purpose, the mineral matter falls on a revolving cone beneath the body of the wagon and is thus uniformly spread over the surface. If the covering is distributed by hand, the material should be placed in piles from 25 to 50 ft apart alongside the roadway prior to the

application of the bituminous material. A gang of 10 spreaders working efficiently can cover from 12 000 to 20 000 sq yd per day of 8 hr.

Penn. State Highway Dept. Specifications for Covering Material (17). "Pea gravel shall be composed of hard, tough, durable pebbles, free from loam, silt, clay or other foreign substances, and 100% shall pass thru a ½-in screen: 35 to 50% shall pass thru a ¼-in screen; 10 to 20% shall pass thru a ⅛-in screen; and not over 10% shall pass thru a 10-mesh sieve.

"Stone chips shall consist of trap rock or other approved stone equally as hard, tough and durable, newly broken, with sharp edges, and of uniform quality thruout, free from dirt or disintegrated stone or screenings or other foreign matter. They shall be of such size as to pass a ⅝-in screen, with the larger sizes predominating, and shall be free from dust."

Conclusion Am. Soc. C. E. Spec. Com. Mat. Road Cons. (16g). "After the bituminous material is applied it should be covered immediately with the toughest grit obtainable that will pass thru a screen with openings not less than ⅜ in nor greater than ⅝ in, just enough of such material being used to cover the bituminous material. It is advantageous, but not entirely necessary, to roll with a steam roller after the application of the grit."

French Practice of Constructing Tar Surfaces on Broken Stone Roads (55), as reported to the 3rd Int. Road Cong., is as follows:

It consists of spraying during dry and hot weather the previously clean-swept road with fluid tar heated to 70° C (158° F) at least, or with a heavy tar oil from coal. The tar penetrates into the joints of the stone and incorporates itself with the road to a depth not exceeding 2 to 3 cm (0.8 to 1.2 in). The dressing of tar per sq m varies from 0.8 to 1.5 kg (1.34 to 2.5 lb per sq yd) or even more, up to 2.5 kg (4.2 lb) in certain cases, the heavier dressing being in the case of original tarring, and the lighter in the case of subsequent maintenance.

British Practice of Constructing Tar Surfaces on Broken Stone Roads is fully covered in the specifications (see Art. 8) adopted by the Road Board of England.

Connecticut Practice in the Construction of Asphaltic Oil Carpets on Gravel Roads by C. J. Bennett, Highway Commissioner. " Bituminous carpets on gravel roads are of two classes, applied cold or hot. It may be, however, assumed that for a gravel road carefully built, a cold treatment either of oil or tar will give better results than the hot treatment, since the treatments may be more frequently renewed and a great number can be made before the road needs reconstruction. On the other hand, a hot carpet is of itself more stable and will last a considerable length of time. Any of the bituminous carpets, however, are liable to roll up and mud up in wet weather and should be only used with great care, particularly as to the character and amount of material applied and the method of application. In no case, should the amount exceed ¼ gal per sq yd of surface treated per application. It is far better to make repeated applications than to put on too much at once. These carpets should be covered with proper clean covering material, either sand, coarse sand, gravel or stone chips in such a manner as to completely cover the surface of the road and to provide sufficient material so that the bituminous material contained in the carpet should not exceed 15% by weight of the total carpet covering. Care should be taken that a proper bond is formed between the carpet and the road body. This may be done by sweeping exceedingly clean."

Mass. Highway Comm. Sand and Oil Layer Method of constructing a bituminous surface on a roadway of sand is described in detail in the specifications contained in Art. 8.

The Commission states (43) that "these can be used only where a sand of the right quality is available, and under present methods can be used only where the traffic is mostly light teams and automobiles; they will not stand up if they are used

by many heavily loaded teams every day. The layer roads are more easily rutted by teams than are the mixed roads, for two reasons: First, one cannot use as heavy a quality of asphaltic oil because it cannot be made to mix with the cold sand; second, because by the layer method one can never secure as even a mixture of the sand and oil on every part of the road.

"The traffic that has been carried successfully as shown by the traffic census taken in 1909, 1912 and 1915 is about as follows, the figures being the average daily traffic: Eastham, 1905 road, layer method; 20 heavy teams, 17 light teams and 258 automobiles."

Maryland Method of Constructing Large Mileage Under One Contract, as described by Fulweiler (16e), is as follows:

"In the organization for re-surfacing, where a considerable amount of this work is to be done, attention is called to a plan by which a very large amount of such work has been done on the State roads in Maryland. Under this plan the State furnishes and applies the necessary stone covering, purchasing the stone and having it delivered in piles along the road-side in the early spring, when the price of teams is quite low. From a schedule prepared by the State engineers, showing the location of the roads to be treated, a price is agreed on, and a contract drawn up whereby the manufacturer of the material agrees, for a unit price per square yard, to sweep surfaces which have been previously treated with bituminous material, and also surfaces which have not been thus treated, and a unit price per gallon for applying the material, at the approximate rate shown on the schedule. In the contract for 1913, it was specified that all work should be completed before July 31, with a penalty clause of $25 per day for every day that this time was exceeded. There was a further clause in which the company agreed to pay the State $25 per day for every day that it was delayed thru breakdowns or the failure of material to arrive, and the State agreed to pay the company the same amount for every day that it delayed the application of the material thru inability to cover it. This contract involved some 34 pieces of road in nine counties of the eastern shore of Maryland, amounting to about 118 miles, and containing 976 071 sq yd. On this was applied 342 785 gal of material, at a rate varying from 1/8 to 1/2 gal per sq yd, and averaging 0.366 gal per sq yd. This was covered with stone chips averaging 12 lb per sq yd.

"Two motor trucks were used in this work, and they arrived about May 26th, altho, owing to bad weather and some delay in organizing the gangs, work was not commenced until May 28th. One truck finished practically half of the work on July 18th, and the other finished on July 30th. The State maintained two gangs, of 12 men each, each under an inspector, for applying the stone chips, the company sweeping the roads and furnishing and applying the binder.

"Practically this same form of contract had been in force during 1912, but during that year the work was not laid out according to schedule, and the trucks frequently had to make long jumps between the different pieces of work. This caused considerable loss of time, which was furthermore augmented by difficulty in securing proper labor. As the result of the experience of 1912, the work was laid out more systematically in 1913, and men composing the covering gang in one case were held thruout the season. The effect of having experienced men for covering is well brought out in the following table, which summarizes the operations of the 2 years, the time being given in truck-days. In 1913 the decrease in time lost in transit, repairs, and delays, is quite striking, as is the average increase in the quantity applied per day." See Art. 8.

	1912	1913
Sunday and holidays	21	20
Repairs and delays	22	6
Rain	5	9
Transit	34	18
Applying material	57	72
Total elapsed days	138	125
Percentage of days worked	66%	72%
Percentage of days material applied	41.5%	57.5%
Average number of gallons applied per day	2 860	4 760
Average number of square yards treated per day	8 230	13 550

8. Specifications for Construction

Am. Soc. Mun. Imp. 1917 Specifications for Hot Tar Surface Treatments, are as follows:

"**Description of Bituminous Surface.** The bituminous surface shall consist of one application of refined tar covered with a layer of No. 1 broken stone (passing thru ⅝-in and over ¼-in screen) constructed as hereinafter specified.

"**Refined Tar.** Refined tar used in the construction of the bituminous surface shall conform with either one of the specifications covering the chemical and physical properties of refined tars included under the item entitled 'Refined Tars for Surface Treatments.' See Art. 5.

"**Heating Refined Tar.** The refined tar shall be heated in kettles or tanks so designed as to admit of even heating of the entire mass, with an efficient and positive control of the heat at all times. It shall be heated as directed by the Engineer to a temperature between 93° C (200° F) and 121° C (250° F). All refined tar heated beyond 121° C (250° F) shall be rejected. No tar shall be heated in kettles or tanks containing any oil or asphalt cement. Before changing from one type to another, kettles or tanks shall be scrupulously cleaned in order to avoid mixtures of the two. Any mixtures of different kinds of bituminous materials shall be rejected.

"**Thermometers Furnished by Contractors.** The Contractor shall provide a sufficient number of accurate, efficient, stationary thermometers for determining the temperature of the refined tar in kettles or tanks.

"**Preparation of Surface of Road.** Prior to the application of the refined tar, the surface of the broken stone road, when thoroly dry, shall be swept clean of all dust, dirt or other loose material with horse or power-drawn brooms and bass or other fine fiber brooms, or with stiff fiber hand brooms and bass or other fine fiber brooms, as directed by the Engineer. When the cleaning is completed the upper surface of the No. 3 broken stone (passing over 1¼-in and thru 2¼-in screen) shall be exposed, forming a clean mosaic surface.

"**Application of Refined Tar.** After the surface shall have been cleaned to the satisfaction of the Engineer, and when thoroly dry, the refined tar shall be uniformly applied over the prepared surface of the road by means of a pressure distributor as hereinafter specified (see Art. 6) and in accordance with the directions of the Engineer. The refined tar, when applied, shall have a temperature between 93° C (200° F) and 121° C (250° F). The total amount of refined tar to be used in the construction of the bituminous surface shall be applied in one application and shall not be less than ¼ nor more than ½ gal per sq yd, the precise quantity being determined by the Engineer.

"**Application of No. 1 Broken Stone.** Immediately after the application of the refined tar, a layer of dry No. 1 broken stone, not to exceed ⅜ in in thickness, shall be spread and broomed as directed by the Engineer over the surface of the refined tar and shall be at once rolled as directed by the Engineer with a roller weighing between 8 and 15 tons.

"**Seasonal and Weather Limitations.** No refined tar shall be applied when the air temperature in the shade is below 10° C (50° F), except by the written permission of the Engineer.

"**Measurement and Payment.** The quantity of broken stone road with bituminous surface to be paid for under this item shall be the number of square yards, measured horizontally, satisfactorily completed in accordance with the specifications. The price stipulated in this item shall include the furnishing, crushing and screening of the different sizes of broken stone, the placing, rolling and watering of the broken stone, the heating and distributing of the refined tar, and all materials, work and expenses incidental to the completion of the broken stone road with bituminous surface except the furnishing of the refined tar, which will be included for payment under the item entitled 'Refined Tars for Surface Treatments.'"

The General Directions and Specifications Relating to Hot Tar Treatment of Roads, Adopted by the Road Board of England, are as follows:

"1. Surface tarring may be advantageously applied either to an old road surface in good condition or to a new surface after it has been consolidated and dried, but the tarring should never be carried out unless the road is thoroly dry. If there are any depressions, pot-holes, waves, grooves, or other irregularities, these should, as far as practicable, be made good before tarring is commenced, so as to provide an even surface.

2. Painting and spraying machines get thru the work of tarring more rapidly than application by hand, and consequently are to be recommended, but hand work gives satisfactory results, and the selection of the method to be employed must be largely determined by the available supply of efficient labor.

3. If it is intended to tar an old surface it is advisable to take advantage of the early months of the year to scrape or brush the road during wet weather as a preparation for subsequent tarring, and especially to keep the road free from caked mud.

4. If the crust of a road is thin at the sides, but adequate in the center, the sides should be strengthened and consolidated before application of tar to the surface.

5. In resurfacing any road the surface of which is afterwards to be tarred, stone chippings, and not fine material, should be used for binding.

6. The road whilst being tarred should be closed to traffic over half its width, or where practicable, over its whole width.

7. The road should be thoroly brushed and cleaned before application of the tar. Wet brushing should be used sometime previous to dry brushing, if there is any caked mud. Any method of brushing may be used which will scour and clean the road thoroly, the best being horse brushing, followed by hand brushing.

8. Tar should be used for surface tarring which complies with either Road Board Specification for Tar No. 1 or Road Board Specification for Tar No. 2, but if the heavier grade of the tar is used, care should be taken to apply it only when the road is dry and well warmed by the sun's rays, otherwise it will not flow freely. See Art. 5.

9. The tar should be heated to its boiling point at convenient positions on the works, and should be applied as hot as possible, so that it may flow freely. The desired temperature will be generally found in practice to lie between 104° and 116° C (220° and 240° F) for Tar No. 1, and between 127° and 138° C (260° and 280° F) for Tar No. 2.

10. In order that the tar should be applied to the road as hot as possible, it is advisable if the method of application is by hand, to use flexible pipes to convey the tar from the boiler to the point of application. If these are not available it will be found convenient in case of hand pouring, to use 3-gal cans specially constructed for the purpose, fitted with spouts leading direct from the bottom of the cans, and being not less than 1½ in in diameter at the orifice.

11. Immediately on application, the liquid tar should be brushed so far as necessary to ensure regularity in thickness of the coating.

12. The quantity of tar required will vary according to the physical conditions of the road, but generally, in the case of a road to be treated with tar for the first time, the quantity should be 1 gal to coat from 5 to 7 sq yd.

13. If the road must be opened for traffic before the tar has set hard, grit should be spread on the surface to prevent the tar from adhering to the wheels of vehicles, but gritting should be delayed as long as possible, and the quantity of gritting material to be spread should be no more than sufficient to prevent the tar from adhering to wheels. Stone chippings, crushed gravel, coarse sand, or other approved material, free from dust, not larger than will pass thru a ¼-in square mesh should be used for gritting, in quantity not exceeding 1 ton for 300 to 350 sq yd if grit is used, and 1 ton for 200 to 250 sq yd if coarse sand is used.

14. Precautions should be taken to prevent liquid tar passing directly thru drainage gratings or outlets.

15. For the safety of the public precautions should be taken by lighting, watching, and warning. Notice boards should be placed in suitable positions. It is specially desirable to place warning notices at points in the neighborhood of the work where other roads join or cross the road being tarred, to enable motorists and cyclists to avoid the obstructed road by taking any available alternative route.

16. On heavily trafficked roads it is advisable to apply a second coat to either the whole width or from 9 to 12 ft of the center of the road in quantity of 1 gal to coat from 8 to 10 sq yd about 2 to 3 months after the first application.

17. Surface tarring should be renewed annually on all important roads, and as required on roads with light traffic. On such re-coatings the quantity of tar to be applied will vary with the extent to which the previous coating of tar has been removed by weather or by traffic.

18. Two or more samples of the tar used should in all cases be kept in quart tin cans, and be carefully labelled, including particulars fixing the locality or length of the road on which the tar was used. The Road Board will arrange with the National

Physical Laboratory to submit a selection of these samples to a series of chemical and physical tests with a view to the results being recorded for future reference, and surveyors will from time to time be invited to send samples for the purpose.

19. In all cases careful record should be kept of the condition of the road surfaces in winter and summer, both before and after tarring, the quantity and quality of tar used, the superficial area covered, the state of the weather when the work is being done, the time occupied in actual work, and in waiting whilst work is stopped owing to wet weather, the number of men employed, and full details of the cost of labor and material.

20. Surveyors are invited to send records to the Road Board to be classified and published for general information. Forms for these records will be supplied by the Board.

21. Surveyors are recommended to have samples of the tar supplied to them under contracts properly tested by a qualified analytical chemist."

Md. State Roads Comm. 1917 Specifications for Tar and Oil for Cold Application are as follows:

"**Sweeping.** The road surface shall be swept with a rotary rattan broom drawn either by horse or motor power in such a manner as to remove from the surface all dirt or other foreign materials, and should the rotary sweeper not remove all the dirt or foreign material, giving a clean surface, then the contractor will be required to scrape the foreign material from the surface with hoes or other tools, and cleanly sweep it with rattan brooms by hand.

"**Applying the Material.** No material shall be distributed except by a motor-drawn pressure distributor of a type satisfactory to the engineer, and no material shall be applied when the surface is wet, frosty, or when, in the opinion of the inspector it is unfit to receive the application. All material will be applied at the rate specified by the inspector, but in no case is more than ⅓ gal of material to the square yard to be applied to the surface in one application and where ½ gal per sq yd is applied, it shall be put on in two applications. When two applications are specified, all the stone chips shall be evenly and uniformly distributed over the surface as hereinunder specified, after the first application of oil or tar has been made, and then the second application shall be made, but in no case shall more than 24 hr elapse between the first and second application of the oil or tar. In order that the traveling public may be accommodated as much as possible, the contractor will apply the oil to one-half of the road surface at a time, and as soon as one truck load is applied to one side of the road it will be covered with chips by the contractor or the State, as the contract provides.

"The contractor will so arrange his work that the distributor will be on the road ready to spread oil or tar by not later than eight o'clock in the morning, and should the contractor at any time refuse or neglect to be ready to spread oil or tar by eight o'clock in the morning, when the spreading of the stone chips is being done by the State Roads Comm., then the contractor is to pay the State Roads Comm. $3 per hr or fraction thereof for all delays due to this cause. Should the State Roads Comm., on account of not having sufficient men to spread the stone chips, delay the contractor in spreading oil after eight o'clock in the morning, then the State Roads Comm. will pay the contractor $3 per hr or a fraction thereof, for all time due to such delays, but it is clearly understood that the contractor will so arrange his work that the oil or tar applied can be covered with stone chips by the close of the working day in that locality unless otherwise authorized by the inspector.

"**Spreading Stone Chips.** The stone chips or gravel required to be spread on the road after the application of the oil by the contractor will be deposited along the road on one side or the other in approximately even piles, at regular intervals of 25 ft. These chips or gravel will be funished in these piles by the Commission without expense to the contractor. Approximately 80 tons will be used to a mile of 14 ft surfacing to be treated. The contractor will bid a price per ton for the chips spread on the road from the piles. Railroad weights will be used as a basis of payment in all cases where the material is hauled on the railroad and quarry weights when hauled direct from the quarry to the road.

"The contractor will be required to spread these chips or gravel evenly and uniformly over the surface of the road immediately after the oil is applied and fill in all holes or inequalities, and in no case must more than 2 hr elapse between the application of the oil and the complete covering of the surface with chips or gravel, and under no circumstances will work be permitted to remain uncovered during the night, and the contractor must so arrange the application of the oil so that all the surface can be com-

pletely covered with chips or gravel during the working day. The term 'evenly and uniformly' shall be construed to mean that each and every square yard of surfacing shall have the same amount as each other square yard within a variation of not more than 10%, except in such places as the inspector may direct to fill depressions or holes."

The Los Angeles 1917 Specifications for the Construction of an Oil Carpet on Street Roadways are as follows:

"Where there are cement or brick gutters, a small trench not more than 1 in in depth at the outer edge of the gutter, shall be trimmed out to meet the surface at a point not more than 6 in from the edge of the gutter, and a small ridge of sand or screenings shall be maintained on the outer edge of the gutter to keep oil from running on the gutter. This ridge shall be removed after the oiling is completed.

"Oil shall then be evenly distributed over the entire surface of the roadway in a volume equal to 1 gal by measure per sq yd of surface. After a lapse of not less than 24 hr, sand of a quality hereinafter specified, shall be uniformly spread upon the oiled surface in such quantity as will absorb all surplus oil. The roadway shall then be brought to a smooth and even surface by use of hand brooms or rakes, and all surplus material shall be swept from the street.

"Oil shall again be distributed over the surface as before in a volume equal to ½ gal by measure per sq yd of surface. After a lapse of not less than 24 hr sand shall again be spread upon the oiled surface and the road-bed brought to an even surface, as hereinbefore specified. The surface shall then be rolled with a roller having a compression of at least 200 lb per in width of tire, until it has received the utmost compression possible and is uniformly smooth and free from bumps, sags or loose spots. The surface of the road during rolling shall be sanded and swept whenever necessary to secure a uniform coating of oil and sand, and on completion of the rolling the street shall show no stickiness.

"The total amount of oil used shall not be less than 1½ gal per sq yd of the roadway surfaced. In the process of oiling care must be taken not to soil the curbs or walks. After the oiling of a roadway has commenced, it shall be carried on diligently to its completion. Oil shall not be applied to the surface of a roadway while it is in a wet condition.

"After the final rolling, the road-bed shall be trimmed wherever necessary and sand shall be distributed thereon and brought to a smooth and even surface 1 in in thickness by the use of hand brooms or rakes.

"Oil shall be applied in a uniform sheet by means of pressure distributing sprays only and shall be at such temperature within the limits hereinafter specified as is determined by the inspector to be desirable. The pressure sprays shall be operated at a uniform pressure of not less than 20 lb per sq in. Oil wagons or trucks shall be provided with tires of such width that the maximum pressure on said tires shall not exceed 400 lb per sq in of tire."

Mass. State Highway Comm. Specifications for Sand and Oil Layer Work (30b) are as follows:

"Grading. The road shall be graded for a width of 21 ft in cuts and 25 ft on fills. The slopes outside the graded roadway shall be left in a neat condition.

"Subgrade. Any clay or other material in the subgrade which, if left, would cause frost action detrimental to the road surface, shall be removed to the depth ordered by the engineer and replaced with suitable material, and any sandy places shall be hardened as ordered. For this purpose, sandy loam or clay may be used, but if used, only enough of these materials shall be placed on the subgrade to carry the travel while the surface is being formed, and in no case shall the depth of such hardening material exceed 3 in after rolling. The subgrade shall be shaped to correspond with the proposed cross-section of the finished road and shall be rolled with a horse roller, unless otherwise ordered.

"Application of Oil. On the roadbed prepared as hereinbefore described, asphaltic oil shall be applied for a width of 15 ft, unless otherwise ordered. The oil shall be shipped to the nearest railroad freight station in tank cars and transported to the work in suitable distributor carts. It shall be heated in the tank cars or distributor carts, so that when applied it shall have a temperature of not less than 82° C (180° F) nor more than 121° C (250° F). The oil shall be applied to the road by a pressure distributor which will spread it evenly over the surface, leaving no spots or streaks uncovered, and no overlapping will be allowed. The distributor shall be so arranged that the operator can control the flow and can cut out sections so as to vary the width

of the road covered. If 2 gal of oil per sq yd are to be used in forming the surface, the oil shall be distributed in 3 applications of approximately ⅔ gal per sq yd. If 1½ gal are used, there shall be two ¾-gal applications.

"Construction of Sand and Oil Layers. Immediately after the oil is applied, a uniform layer of sand shall be spread over it, the depth of the sand to be approximately 1¼ in for the ⅔-gal application, and 1½ in for the ¾-gal application. Each layer of sand and oil shall be rolled with a horse roller, and if ordered, the road, before its acceptance, shall be rolled with a steam roller. During the rolling, sand shall be applied to absorb any oil flushing to the surface. Each layer of sand and oil shall be allowed to stand a sufficient length of time so the oil will mix with the sand, and there shall be no surplus sand or free oil on the surface when the next application of oil is made.

"Materials. The asphaltic oil used shall be as ordered, but in no case shall oil with a viscosity of less than 250 sec, or more than 600 sec, Lawrence viscosimeter at 100° C (212° F), be used. The sand used shall be clean, sharp and free from adventitious materials of all kinds, but if so ordered may contain not over 5% of clay or loam. It shall contain no stones larger than ½ in in their longest dimensions, or more than 30% passing a 50-mesh sieve.

"Finishing and Acceptance. If at any time before the acceptance of the work any soft or imperfect places develop, the material at these places shall be removed and replaced with new material and rolled until thoroly compacted and until the joints between the new and old work become invisible. Any inequalities in the surface shall be removed by scraping with a road machine, or other suitable scraper. After the surface has been completed to the satisfaction of the engineer, and before the acceptance of the work, a light covering of sand shall be spread evenly over the surface. The surface of the road when completed shall have a crown of ½ in to the ft.

"Climatic and Weather Conditions. No bituminous work shall be done during rainy weather, nor when the weather conditions as to temperature or otherwise are unfavorable for obtaining satisfactory results."

9. Construction Cost Data

The cost of constructing thin bituminous surfaces on broken stone and gravel roads varies from 2 to 10 cents per sq yd. The examples cited give average data covering the details of construction.

Philadelphia (24c). Table I gives the cost of labor and materials used from 1913 to 1916 in the construction of bituminous surfaces with refined tars and asphalt cut-back. Table II gives the detailed costs of construction and retreatments in 1916.

Table I

Labor and Material	Unit Costs			
	1916	1915	1914	1913
Torpedo gravel, per 2000 lb, delivered on the road	$2.10	$2.03	$2.14	$2.50
Trap rock chips, per 2000 lb, delivered on the road	2.02	1.94	2.30	2.30
Tarvia A, per gallon applied	0.085	0.085	0.085	0.085
Tarvia B, per gallon applied	0.07	0.0692	0.07	0.07
Ugite hot, per gallon applied	0.08	0.08	0.09	0.09
Ugite cold, per gallon applied	0.064	0.06	0.08	0.08
Asphalt cut-back, per gallon applied	0.1403	0.0791	0.117	0.12
Asphalt, 150 penetration, per gallon applied	0.0795	0.0791	.....	.....
Asphaltic road oil, per gallon applied	0.0588	0.0484	0.0523	.....
Laborers, per 8 hr day	2.00	2.00	2.00	2.00
Foremen, per 8 hr day	4.00	4.00	4.00	4.00
Asst. foreman, per 8 hr day	3.00	3.00	3.00	3.00
Teams, per 8 hr day	4.80	4.48	4.75	5.20

Average labor cost, per sq yd, for hand and machine sweeping, chipping and clean-up during 1915 .... $0.0105
Average labor cost, per sq yd, for hand and machine sweeping, chipping and clean-up during 1916 .... 0.0114

Table II

*Hot application. †Cold application.

"**Asphaltic Oil Surface on Gravel Road, Cairo, Ill.** (46). The following figures do not include contractor's profit or overhead expenses. Total length of road treated, 8200 ft; total sq yd of road treated, 16 400; condition of old gravel road, fair; kind of bituminous material used, Aztec liquid asphalt; amount of bituminous material used, ⅕ gal per sq yd; amount of torpedo gravel or stone chips, sand, 0.006 tons per sq yd; average length of haul, ⅕ mile; general condition of weather, fair; rate of pay for labor, 15 cents per hr; teams, 40 cents per hr.

Table III.—Itemized Cost of Work

	Total Cost	Cost per Sq Yd
*Superintendence, engineering and inspection	$ 34.20	$0 0021
Bituminous material, 8184 gal at 0 047 cents, f. o. b. siding	384.85	0034
Torpedo gravel and stone chips, 66½ cu yd at 0 59 cents f. o. b. siding	39 25	0024
Heating and applying bituminous material, demurrage, etc	51 85	0032
Spreading torpedo gravel and stone chips, sand	51 66	0031
Sweeping and cleaning old road	[illegible]	00034
Depreciation on equipment	*	*
Freight on equipment	88 20	.0054
Total cost	$656 86	$0.0399

*Indicates paid or furnished by the Ill. State Highway Dept.

"**Asphaltic Oil Surfaces in New Jersey** (39). By light road oil is meant a road oil with an asphaltic base which can be applied at an atmospheric temperature of 21° C (70° F) and by the use of the words heavy oil is meant an asphaltic oil which can be applied only after heating to a temperature of approximately 132° C (270° F). On a road surface which is in good condition and where the travel is light and moderate, light oil is applied and covered with sand. Where the road is in similar condition but is submitted to heavy thru travel or extra-heavy local travel, heavy oil and ½-in stone is spread on the application and rolled. Where the roads are in poor condition, heavy oil and a mixture of 50% of ¾-in stone and 50% of ½-in stone are applied and rolled. Roads badly rutted or containing holes are first patched by either heavy bituminous binder and 1½-in stone or by cold bituminous binder and stone. The county furnishes the oils, the contractor unloads same and applies them, after first cleaning the road. The county then covers them with suitable materials, and in case of stone compacts the covering by rolling. The county's work is done by day labor. The following are unit costs which prevailed during the year 1916, the units given being per square yard of surface treated.

"Light Oil Treatment: 28 lb of sand delivered in wagons at $1 per ton cost $0.014; ½ gal of oil f. o. b. tank car R.R. siding, cost $0.02945; application cost $0.007; cleaning cost $0.0025; and spreading sand cost $0.0020; making a total cost per sq yd of $0.05095.

"Heavy Oil Treatment: 48 lb of broken stone alongside of road, at $2 per ton, cost $0.048; ½ gal of oil f. o. b. tank cars R.R. siding, cost $0.0175; spreading ½ gal of oil cost $0.00875; cleaning road cost $0.0025; spreading stone, $0.0025, and rolling stone, $0.002; making a total cost per sq yd of $0.08125."

Massachusetts Asphaltic Oil Surface. Dean (16c) states that "The average cost during 1910 was a little less than $0.08 per sq yd, and, during 1911, a little more than that price, with labor costing from $1.75 to $2.00 per 8-hr day, and asphaltic oil costing $0.06 per gal delivered in tank cars. The detailed cost on an average road is as follows:

	Per Sq Yd
Cleaning and sweeping	$0.0066
Patching old surface	0.0016
Cost of oil	0.0319
Heating oil	0.0031
Delivering oil	0.0038
Distributing oil	0.0029
Furnishing sand beside road	0.0165
Spreading sand	0.0073
Watering	0.0012
Rolling	0.0002
Supervision	0.0025
Total	$0.0766

"The road mentioned was treated with ½ gal of heavy asphaltic oil in two ¼-gal applications. The average haul was 2 miles for the oil and 2½ miles for the sand. No allowance is made in the foregoing detailed statement for rental or depreciation of machinery, or for profits to contractor, the work being done by labor force account."

Table IV.—Cost of Asphaltic Oil Treatments at Portland, Maine, in 1915 (20)

Street	Sq Yd	Cost per Sq Yd	Gal per Sq Yd	Type of Road
Beacon	1 874	$0.0222	0.23	Broken stone
Congress	5 364	0.0365	0.51	Broken stone
Deering's Oaks	12 434	0.0196	0.30	Gravel
Pine	2 230	0.0284	0.36	Gravel
Stevens Ave	8 186	0.0262	0.38	Broken stone
West	2 451	0.0272	0.33	Gravel
Western Promenade	9 958	0.0142	0.19	Broken stone
Woodford	6 396	0.0248	0.30	Broken stone

Massachusetts Sand and Oil Roads Constructed by the Layer Method (43). "Twenty-five and one-half miles have been built by the Commission since 1905. The surface of these roads has cost from 21 to 33 cents per sq yd, the average cost being 26 cents per sq yd. For a road 18 ft wide this would be $2750 a mile, to which should be added the cost of grading, culverts, etc."

England. The cost of surface tarring varies from 1.25 cents per sq yd for crude tar obtained locally in country districts, where wages are low, to 3 and 4 cents where distilled tar is used and prices generally are higher. The average cost of constructing 2 303 000 sq yd of tar surface in Birmingham in 1917 was 2 cents per sq yd.

France. The average cost of tar surface treatments in 1914 was 2 cents per sq yd.

MAINTENANCE

10. Causes of Failure

The causes of failure of bituminous surfaces are numerous. They may be considered from the standpoint of the condition and character of the original surface, the material used, the method of construction, and local conditions.

Condition of Surface. The failure of bituminous surfaces from the standpoint of the character of the original surface is many times due to failure on the part of those in charge to place the surface in satisfactory condition before the application of the bituminous material. Many cases are noted where bituminous materials are applied over a surface in which are found many pot-holes and ruts, or which is dirty, due either to accumulated dust and dirt or to the original method of construction. In many cases a damp condition of the surface or subsurface has resulted in failure.

Effect of Subsurface Moisture on Bituminous Surfaces. Adler (14b) and (14c) states that "All bituminous materials will deteriorate to some degree on exposure to the air and weather. Well-drained macadam road crusts having a complete bituminous seal, have been found to contain a very appreciable amount of moisture during the early spring, drawn undoubtedly from the subgrade and adjacent earth shoulders. This moisture in the body of the road, under freezing temperature, does more damage to bituminous surface films than any other natural agency. As a further illustration of the importance of frost action, it is reported that in extreme Southern States it is possible to maintain bituminous treated gravel roads as a permanent form of construction, in so far of course as this type can be called permanent; while in certain New England States, with careful attention to drainage, it is found impossible to hold the impervious bituminous surface on gravel roads subjected to the heaving and consequent settling of the spring break-up.

"The action of water beneath the surface treatment is perhaps even more destructive than when above the surface. Even a well-drained macadam road, containing the minimum amount of screenings and fine material in its body, and with an unbroken bituminous seal on its surface, will show moisture in the road crust drawn up thru the capillary spaces, during the winter or at the end of any protracted wet spell. A good, live film of bitumen clinging to the surface of the tightly locked stones will withstand the action of this water providing the road itself remains solid. If, however, the film of bitumen is lying on even a thin mat of stone screenings instead of being attached directly to solid stone, and if the situation is further complicated by poor drainage conditions on the road, it will be found almost invariably that moisture will arise thru the body of the road and be held blotter-like, by the fine screenings, which in cold weather will freeze, expand, and lift the bituminous film from the road surface. This results in a breaking of the seal, and frequently in the complete destruction of the surface treatment."

Bituminous Material. From the standpoint of the physical and chemical properties of the material, many instances may be cited in which failure is due to materials not having the proper characteristics for the conditions under which they are employed. The large percentage of volatile con-

stituents contained in certain asphaltic oils has rendered surfaces constructed with them unsatisfactory because of the long period required for these surfaces to set up so that the bituminous material will not track or the carpet thus formed will not creep and form waves and humps. In certain cases the use of light oils on tar or asphalt surfaces has softened the original bituminous surface to such an extent as to render the road or pavement unsatisfactory for use. See Art. 4.

Construction Methods. From the standpoint of construction, failures are due both to the use of too small an amount of the bituminous material and to an excess of material. Improper application, resulting in uneven distribution, is accountable for many failures of bituminous surfaces. A lack of sufficient covering of stone chips or material of a similar character has rendered the surface sticky and mushy. An excess of covering has caused the formation of a mat of varying thickness.

Unsuitability. There are numerous instances where bituminous surfaces have been adopted under conditions which call for the construction of bituminous concrete pavements or even some type of block pavements. A mat type of construction, which has been employed to a considerable extent, has proved inefficacious in cases where the amount of motor-car traffic was not sufficient to iron out satisfactorily the calk holes caused by the horse-drawn vehicle traffic. See Art. 3.

11. Methods and Cost of Maintenance

Patching. Continuous repairing methods are essential in order to keep the surface of the roadway in satisfactory condition and to reduce the annual cost of surface treatments to a minimum. Methods of patching should be employed which will prevent the road metal in patches from being displaced by traffic. For filling small depressions and ruts of ½ in or less in depth, a very adhesive quick setting bituminous material should be painted over the surface and the depressions filled with tamped road metal which will pass over a ½-in screen and is free from dust. Pot-holes, and ruts having a depth greater than ½ in, should be cut out with vertical sides to the full depth of the depression and then filled with tamped bituminous concrete (see Sect. 10), which may be mixed by using either heated road metal and hot bituminous cement or unheated road metal and bituminous cement especially prepared to set up quickly after being mixed with unheated road metal.

Connecticut Practice in Patching Gravel Roads by C. J. Bennett, Highway Commissioner. "Repairs to roads of this character should be made with the same material used for the superficial coat and preferably by mixing the material with the gravel or sand in making patches. In either type of hot or cold treatment, small patches which are only superficial in their depth can be treated by painting the depressions with bituminous material and adding screenings or gravel to cover, but in deeper depressions, the bituminous material should be mixed with the aggregate and placed in the patches. If the patches are of some extent or depth, the edges should be cut back in order to give a shoulder for the patching material to rest against. Great care should be taken to see that too much bituminous material is not added to these patches; otherwise, they will roll or bunch up above the average surface. In other words, the patches should be of the same consistency as the road surface itself and preferably left slightly below the average."

Patching Methods Used in Montclair, N. J. (23). "The patching this year (1915) is done with stone mixed with bituminous cement at a central point and delivered on the street where needed. For cement, H. G. R. No. 1 was used, obtained from the Headley Good Roads Company, costing 6¾ cents per gal, f. o. b. Philadelphia in tank cars. The stone used was trap, ½-in with ¾-in added for deep holes. Fifty

gallons of the binder were mixed by hand with 7000 lb of trap stone; the stone being spread out level, the binder poured on by hand, and the stones then turned over by shovel. Machine mixing would probably be cheaper, and will be used during 1916. In applying the stone thus prepared, the hole is cleaned of dirt and loose material, the prepared stone spread, and rolled. In some cases the depression has worn so large that the patch extends the full width of the paved strip of the roadway, which is generally 18 ft. Including cost of materials and an average haul of 2 miles to the street, this costs about $7 for the amount above described. Fifty-one thousand gallons of binder were used this year in preparing patching material in this way. This material seems to be just about as durable as the clay-bound macadam which it is used to patch, and therefore does not either rise in humps above the pavement as the macadam wears down, or wear more rapidly and produce holes again."

British Practice in Patching Tar Surfaces (49). "To take out pot-holes, ruts, and similar irregularities in the surface, peck round them and remove the worn granite and other material to a depth of 1½ to 2 in to secure an ample key and body to the patch; carefully brush the hole over with hot tar and fill in with previously tarred 1½ to ¼-in graded material, using the greatest care to ram solid. The patch should be so finished that it is not more than ¼ in higher than the adjacent surface of the road, to allow for shrinkage and further consolidation under traffic. If this course is carefully followed the patch quickly becomes level with the surrounding surface. If a patch is finished so that it sets above the surrounding level the fact that it is harder than the road itself causes traffic to bump upon it both ways; excessive wear takes place on both sides as a consequence; other holes form around it, and the road becomes so bumpy as to be almost unrideable. If the patch is finished below the surrounding level, traffic quickly wears down the edges of the road around it, the tar painting breaks away and allows the penetration of water."

Retreatments. The life of a bituminous surface and its economical use depend primarily upon traffic conditions, the method of construction, and the nature of the bituminous material used. With the heavier grades of bituminous materials adaptable for this work, if the road is subjected to a normal traffic for which the method and material are economical and suitable, retreatment is necessary every 1 or 2 years. Under traffic conditions demanding some other type of construction, it may be necessary to retreat the road twice each year, as is done in the case of the Avenue du Bois de Boulogne in Paris. A retreatment can generally be accomplished by using a smaller amount of bituminous material than was used in the first treatment (see Art. 9, Table II). The same care should be taken in preparing the road surface as is used in the original treatment. It is essential, in the case of blankets that bare spots should be painted first and then the entire surface covered with as light an application as practicable. If an amount, sufficient for the formation of the blanket over the bare spots, is applied for the entire surface, an excess of bituminous material will exist over much of the roadway and the usual result will be the formation of a soft, uneven, mobile mat, which will soon be displaced by heavy weight traffic.

Philadelphia Practice in Retreatment of Tar and Cut-Back Asphalt Surfaces. See Art. 9 for amounts of materials used and costs per square yard.

Massachusetts Practice in Retreatment of Tar and Asphaltic Oil Blankets (30c). "For the first treatment is used about ½ gal of oil, with a viscosity of between 40 and 50 sec, Lawrence viscosimeter, at 100° C (212° F), followed in the second season with about ⅜ gal of oil with a viscosity of about 100 sec, and the third season from ⅙ to ¼ gal of similar oil. After that not over ⅙ gal should be needed, and retreatment will probably not be necessary every year. After the second or third year oil with a viscosity up to 200 sec can be used to good advantage."

Maine Practice in Retreatment of Tar Surfaces on Gravel Roads. Sargent (50) cites as an example a gravel road which carries for 4 months in the year an average traffic of over 1200 vehicles per day and on Sundays and holidays a traffic running from 3000 to 3500. Since 1915 this road has been maintained by early patching and dragging, and shaping with gravel. This work has been started as soon as the snow has

left the ground and the surface of the road began to soften up, which usually was about the middle of April. Most of the surface treated gravel breaks up after freezing and thawing begins in the fall. After the snow leaves in the spring the tar crust breaks up into scales of perhaps ¼ to ½ in in thickness and in sections having a surface area anywhere from 1 sq in to 1 sq ft.

"In 1915 the first retreatment with Tarvia-B was made in June, using 0.3 gal per sq yd. About the middle of August, a second application was made, using 0.2 gal per sq yd. In 1916 and 1917, about May 20, or as soon thereafter as the weather was warm and the roadway dry, the surface was prepared by sweeping with a horse sweeper and hand brooms to remove any loose particles of dirt or dust. The tar was applied at the rate of 0.4 gal per sq yd of surface. The surface treatment was 16 ft wide, the same width as the gravel surface, the application being made with automobile trucks fitted with spray bars covering 8 ft. The tar surface was covered with stone using about 1 cu yd to 100 sq yd.

"If there are any pockets of dust or soft places in the gravel, the tar surface will break up, and such places have to be immediately attended to by the patrolman. Patching is done in two ways, either by mixing sand and Tarvia-B together in the proportion of 1 gal of tar to 1 cu ft of sand and putting that in the hole and then patting it down with a shovel, or, if the broken place is found soon enough, the patrolman simply gives it a little brush of tar with an old broom. Sometimes a light sprinkle of sand is thrown over the tar. The edges of the tar treatment are inclined to crumble off as a result of traffic turning out over them and a good deal of the patrolman's time is taken up with patching the edges with the mixture of Tarvia-B and sand.

"The cost of maintenance on the above section was as follows:

	1915	1916	1917
Patrolman's wages	$ 209.81	$ 329.16	$ 417.53
Extra help	91.28	624.57	450.59
Material	1036.99	1309.49	1250.68
	$1338.08	$2263.22	$2118.80
Inspection	25.10	182.03	175.00
Total cost	$1363.18	$2445.25	$2293.80
Cost per square yard	$0.053	$0.095	$0.08"

Repair and Removal of Bituminous Surfaces. In the case of thin superficial treatments with refined coal tars, water-gas tars and cut-back asphalts, retreatments may be employed for many years, if the work is properly done as in the case of the bituminous surface treatments in Philadelphia referred to in Art. 10. European practice gives instances where tar retreatments have been successful for over 10 years. When carpets of over ½ in in thickness are employed, there is a marked tendency under horse-drawn vehicle traffic for the surface to be displaced by the blows of horses' hoofs, and, when the roadway is subject to heavy weight traffic, waves and other irregularities of the surface soon appear. While it is practicable in some cases to smooth out uneven carpets by the use of planers and other special devices, it is usually impracticable to maintain carpets, under the traffic noted, in satisfactory condition for more than 1 to 5 years. When the carpet is in such condition that retreatments and repair methods are inefficient, the removal of the bituminous surface is the only economical solution. This may be accomplished by scarifying or by the use of picks and shovels.

Mass. Highway Comm. Practice in Reconstruction of Bituminous Surfaces, as described by Farrington (30c), is as follows: "Any water-bound macadam or gravel surface maintained with oil or tar will have to be reconstructed or reshaped occasionally. With macadam, if not to be reconstructed, the usual custom is to break up the surface, remove the tar or oil if necessary and reshape. The roller picks, or a scarifier, or both, are used for breaking up, followed by a thoro harrowing, preferably using both the

straight tooth and curved spring-tooth harrows. The former completes the breaking up and the latter brings the coarser particles of road metal to the top. Usually some new stone is added and it may be necessary to use some sand or other material, as the voids must be filled to near the surface; but ordinarily there will be sufficient fine material in the old stone. To obtain good results there must be no sand or other fine material on the surface and the stone on top must be clean, but the voids must be filled so the bituminous material will not penetrate far below the surface. This is necessary, not only to avoid the use of an excessive amount of bituminous material and hence increase the cost, but also because with the grade used any surplus bituminous material in the voids will eventually work up and cause the surface to roll.

"About ½ gal of oil per sq yd should be put on in two applications with a covering of sand or other grit after each application. Before applying the bituminous material the road should be rolled with a steam roller, and much of the success of this work depends on a thoro rolling. A final rolling after the bituminous material has been applied and covered is advisable.

"The methods used in forming oil or tar blankets on gravel and the methods of maintenance are similar to those for broken stone, except that for the first application it is essential that the oil or tar used be light enough to penetrate somewhat and thus form a thoro bond with the gravel. In reshaping gravel it is necessary to loosen the surface only enough to shape with a road machine unless there is a thick blanket of oil or tar, in which case this must be removed or thoroly broken up and mixed with the gravel by harrowing."

Connecticut Practice in Reconstruction of Bituminous Carpets on Gravel Roads, by C. J. Bennett, Highway Commissioner. "Reconstruction of roads treated with a superficial bituminous material is a somewhat difficult matter. If much of the material remains upon the surface of the road, it should be entirely removed. In fact, the necessity for reconstruction generally arises from the unevenness of the surface due to the fact that some of the bituminous surface has been worn out or has bunched up into rolls giving the well-known washboard effect. There are several methods of reconstruction, the most radical of which consists in removing the bituminous material, scarifying and resurfacing the road. Good results may sometimes be obtained by treating the rolled bituminous carpet with a light application of non-asphaltic oil which will tend to soften up the surface. After the asphaltic oil has been applied for a short length of time, a planer or heavy road drag may be dragged over the road back and forth until the surface becomes even, after which it may be partially covered with new fine gravel or stone chips, and the patching and maintenance continued as outlined above."

Connecticut Hone or Planer. Ulrich (56) states that "The zigzag hone is constructed of heavy oak plank reinforced by metal straps and ½-in metal cutting edges, which are slotted to give necessary adjustments. The zigzag feature moves the material out from the high points, and distributes it in the hollows. The rear blade is a solid distributing blade, and a hole is cut in the side member, just in front of this blade, to allow any excess material to pass out to the side of the road and not pile up in front of the blade. This hone is about 8 ft wide and 10 ft long. Should the surface prove too hard to yield to this hone, a modification of the Hedley planer is employed. This plane has been built of heavier channels, with an improved method of holding the teeth which allows a quick adjustment whenever necessary. The spacing of the channels carrying the teeth has been changed, and a hole cut in the side channel, just forward of the rear distributing blade, to allow excess material to pass out, as is the case in the zigzag hone."

Asphaltic Oil Carpets Smoothed with Scarifier and Scraper in Riverside, Cal. (29). "Experiments were made with harrows, or toothed scarifiers, but altho they gave a measure of success the teeth were found to wear excessively and did not permit of a sufficiently flexible control. Further experiment applying the rotary disk idea met with greater success, and for several years now scarifiers have been in service with which roughened pavements have been effectively restored to a high degree of smoothness. The disks are 18 in in diameter and are spaced 1 in apart by cast-iron spreaders. The sets are so adjusted that the outer disk on each set is offset 1 in from the track of the near disk on the preceding set. The axles of the disk sets are not quite parallel to the main axles of the scarifier, as it has been found that a slight in-

clination aids in turning the loosened material out of the cuts. This inclination is usually such that with 30 disks all spaced 1 in apart the actual effective cutting width is 28 in. This inclination is kept constant for all disk sets and can be changed by adjusting a pair of bolts on the frame. The entire set of disks is shifted right or left, lifted or depressed, by hand wheels on the operator's platform.

"The method is to loosen the surface of the high spots with the scarifier and follow with a road grader, which cleanly scrapes off the loosened material and leaves it in convenient shape to be gathered and hauled to the yard. These scrapings are kept free from foreign material by sweeping the pavement with a rotary brush just before scarifying it. After having cut the surface down to grade, the depressions are swept by hand, painted with heavy base crude petroleum and the requisite amount of the loose material or scrapings is filled in and tamped. Depressions so filled have given satisfactory service for 5 years. It is not, however, intended to use this method where actual patching of the surface is required; only depressions less than 1 in in depth are treated in this way.

"Scarifying and scraping are done only in the afternoons during warm weather. The scrapings after being delivered in a winrow along the gutter by the road grader, are left until the following morning, when they can be handled more conveniently than when the temperature is high. The usual road crew on this work consists of 2 4-horse scarifiers and 1 road grader, each with 1 driver and 1 operator. Where the surface is rough, progress is at the rate of about ½ mile of 60-ft street per day; but up to 1 mile per day has been made where the roughening had developed to a lesser degree."

SECTION 15

BITUMINOUS MACADAM PAVEMENTS

BY

ARTHUR H. BLANCHARD

CONSULTING HIGHWAY ENGINEER, NEW YORK CITY

GENERAL DATA

1. Description and Definitions

Definition. A Bituminous Macadam Pavement is one having a wearing course of macadam with the interstices filled by penetration methods with a bituminous binder. Adopted in 1915 by the Spec. Com. Mat. Road Cons., Am. Soc. C. E.

Historical Development of the Derivation of Bituminous Macadam. In America, prior to the general use of penetration methods in the construction of bituminous pavements, the term bituminous macadam was widely used to describe bituminous pavements constructed by the mixing method. In 1902, Fred J. Warren, in discussing Bitulithic pavements, made the following statement (55): "The name bituminous macadam may be considered too nearly descriptive to be controlled by any one interest or to be a trade name but, so far as the writer is aware, it was coined for use in connection with letters patent governing methods and proportions of mixing various size mineral ingredients with bitumen, for paving purposes, and in noting the development the writer will confine himself to the experiences of Warren Brothers Co., who control these patents."

When bituminous pavements constructed by penetration methods were used in the United States, the term, bituminous macadam, was applied to them. The term then became indefinite as it was used with reference to two types of bituminous pavements which differed fundamentally in their methods of construction. The general misinterpretation of specifications, articles in the technical press and cost data resulted in a reconsideration of definitions of bituminous pavements in the construction of which broken stone was used.

The Assn. Standardizing Paving Specifications in 1912 adopted a specification for a Bituminous Macadam Pavement, the description of the wearing course being as follows: "Upon the foundation shall be evenly spread stone, which shall pass a 2½-in revolving screen and be retained upon a 1-in revolving screen, to a finished depth of 2½ in. This course shall be dry-rolled with a road roller weighing not less than 10 tons until the individual fragments have keyed together the surface, while even and conforming to the required crown, being left open or porous in order to allow the penetration of the hot bituminous binder." In its Report, the Committee, recommending the above specifications, stated that "In order to avoid confusion we ask that this type of road be known as bituminous macadam pavement, and would suggest that pavements laid by the mixing method be referred to as bituminous concrete."

The Spec. Com. Mat. Road Cons., Am. Soc. C. E., in its 1913 and subsequent reports restricted the use of bituminous macadam to bituminous pavements constructed by penetration methods.

The Am. Soc. Mun. Imp. in 1914 adopted a specification for a bituminous pavement constructed by a penetration method, designating it a Bituminous Macadam Pavement; and in 1915 adopted a specification for a bituminous pavement having a wearing course composed of one product of a stone crushing plant mixed with bituminous cement, designating it a Bituminous Concrete Pavement.

U. S. O. P. R. Prior to 1916 the U. S. O. P. R., in its publications, used the phrases, "bituminous macadam by the penetration method," and, "bituminous macadam by the mixing method." In 1916 it adopted the terms "bituminous macadam" and "bituminous gravel" to designate bituminous pavements constructed by penetration methods using respectively broken stone and gravel for the road metal, and the term "bituminous concrete" to designate bituminous pavements constructed by the mixing method in which the mineral aggregate was composed of broken stone, broken slag, gravel, or similar material, either alone or in combination with other non-bituminous materials.

Status in 1917 (35). "The terms 'bituminous macadam' and 'bituminous concrete' are now generally recognized as the proper designations for the two general classes of pavements of relatively coarse mineral aggregate bound with bituminous material. By the usage of those most conversant with road-building terminology the former is applied to bituminous pavements built by the penetration method and the latter to bituminous pavements built by the mixing method. According to the present understanding of the terms in question, a bituminous pavement built by the mixing method is not a macadam road at all, but a concrete pavement. It should, therefore, be designated as such, with the term 'bituminous' to distingush it from a cement-concrete pavement. It is gratifying to note that the Office of Public Roads has seen fit to conform to the usage *Good Roads* has so long advocated and that has been so generally followed elsewhere. There would seem to be no good reason for using any different nomenclature at present and it is to be hoped that the example of the Office of Public Roads will be followed by writers who still cling to the older and more clumsy forms."

2. Historical Development

History of Bituminous Macadam Pavements in France. Lieut. H. W. Halleck, U. S. Engineer Corps, stated in 1840 (30a) that "for 30 to 50 years, mineral tar, in combination with sand and calcareous matter, has been used in Bordeaux and its vicinity for roads, pavements, floors and the roofing of houses. It was first used, with sand only, in the repair of roads near Bayonne, and being found to answer this purpose, it came afterward to be employed by builders, in its combined form, in preference even to slate and stone; and many houses at Bordeaux are now roofed with it. Regarding the use of bitumen on macadam roads, Lieut. Halleck described the now so-called penetration method as follows:

"'The soil is first removed to a depth of about 5 in, according to the thickness to be given to the road covering, and the earth well rammed; to make it still more firm, small broken stones, about 1 cu in in size, may be driven in. A layer, about 4 in thick of broken stone from ¾ to 1 in in diameter is spread over and smoothed off so

as to give the surface a slight curvature. Over this is poured a very hot and liquid mixture, of ⅓ coal tar, ⅓ pulverized asphaltic stone, of an inferior quality, and ⅓ fine sand. A sufficient quantity should be put on to penetrate all the crevasses of the stone and form a solid mass. After this has become cold, a layer of good bituminous mastic, about 1 in thick is applied, and, while still hot, is covered with a layer of broken stones about 1½ in in diameter, placed close together, but without touching and pressed into the mastic by an iron roller. The thickness of this covering may be varied, according to the wear and tear it will have to resist.' "

History of Bituminous Macadam Pavements in England. In 1820 a bituminous macadam pavement, constructed with a tar cement, was laid in London. Church (24) states that "The principle of constructing a broken stone road, having a binder composed of soft pitch and sand, was the subject of a patent 4 years earlier than the invention of creosoting timber in 1838, with which date the active beginning of the industry of tar distilling is usually associated. In fact, John Henry Cassell secured his patent in 1834, only 22 years after gas was first made in London, so that instead of being one of the latest developments in the industry, this method, so far as it relates to the use of coal tar pitch and sand, is really one of the oldest." In 1901, John A. Brodie constructed the first section of Pitchmac on Princes Ave., Liverpool.

Development in the United States. The penetration method of constructing bituminous pavements has been used extensively in the United States since 1908 in building roads and residential streets, due to its low first cost and the rapidity with which it may be constructed with proper plant equipment and under favorable climatic conditions. The fundamental reasons for the adoption of bituminous macadam pavements by many municipal engineers are given as follows in the introduction of the 1912 Rep. of the Com. Macadam Paving Specifications, Assn. Standardizing Paving Specifications.

"Members of this Committee unanimously agree that water-bound macadam pavement is not a proper permanent pavement to lay, for the following reasons: (1) Since the introduction of the automobile this pavement will not withstand automobile traffic; (2) that bituminous macadam can be laid to withstand this traffic at a cost equal to water-bound macadam when the maintenance is taken into consideration; (3) that a water-bound macadam pavement on residential streets, unless properly sprinkled either with oil or water, is an objectionable pavement on account of dust for the abutting property owners, and unless a great deal of care is taken in sprinkling water, the road is injured to a large extent, and if oil is used it can better be done by original construction using a penetration method."

3. Characteristics

Advantages. The advantages incident to the construction of bituminous surfaces on broken stone and gravel roads enumerated in Sect. 14 are also characteristic of bituminous macadam and bituminous gravel pavements. Many bituminous pavements constructed by penetration methods possess the following advantages: Suitability for horse-drawn as well as motor-car travel; freedom from dust when in exposed localities; low external and internal wear of road metal; low cost of cleaning, watering, and in many cases, of repairs; imperviousness and a certain degree of density of the wearing course; noiselessness and low traction with certain types of bituminous materials; very good sanitary qualities; low cost of plant equipment for methods of construction commonly used in the United States.

Disadvantages. Among the disadvantages attendant upon the use of bituminous macadam and gravel pavements are the following: Increase in cost over bituminous surfaces on broken stone and gravel roads; slipperi-

ness when some bituminous binders are used on certain grades; dependence upon climatic conditions in order to carry on construction properly; variability in results and lack of uniformity in composition of wearing course secured, due to uneven penetration and uneven distribution of the bituminous binder, and segregation of road metal; unstable wearing course due to lack of compaction of the road metal.

Conclusions of Ill. Highway Comm. (40a). "Experience indicates that this form of construction is adapted to moderate traffic roads, that is, where there is no large amount of extra heavy hauling. Where the traffic is composed of automobiles and farm loads not to exceed 2 tons, this form of construction will prove satisfactory, altho possibly not as durable as either concrete or brick. Where traffic consists of heavier loads, wholesale trucks, heavy coal hauling, and loads reaching to 5 and 6 tons, it is believed this form of construction is not at all suitable. It presents a pleasing appearance and is well adapted to horse-drawn traffic as well as automobile traffic, but requires close attention for maintenance, and there is some evidence that during warm weather when the bitumen is least stable there is a tendency for the surface to creep and undulations develop. Bituminous macadam is of doubtful value on those sections of roads so situated that considerable quantities of mud will be tracked on them from adjoining roads."

Conclusions Based on N. Y. State Highway Comm. Practice by Breed (21). "Bituminous macadams in general are not wholly satisfactory. When built on hills it is not safe to apply a flush coat; consequently the road is far from being waterproof when first constructed. This defect is remedied by the traffic, which grinds up the stone and forces it into the voids, but the lack of uniformity in the finished results of these roads has many times been discouraging. In building the bituminius macadam it is impossible to get full consolidation, and consolidation by traffic afterwards makes this type ridgy. As yet the tendency of this type of pavement to creep under traffic has not been corrected. Wonderful examples where this condition has almost been eliminated have occurred, but under similar conditions one road may be a success in this respect and another a near-failure. Oftentimes roads built by the same contractor, under the supervision of the same engineers, using the same care and inspection of materials, will stand well in one case, and in another lose shape and disintegrate in spots within a short time. Among the disadvantages of this type of construction are that it is slippery, has a fairly high cost of maintenance, $493 per mile (16 ft wide) during 1916 and $412 during 1917, and that during repairs the road must be closed to motorists lest it cover their cars with oil and tar. These roads have the advantage of being dustless and easily repaired when street openings are made or when depressions occur."

4. Drainage and Foundations

In Sect. 8, Arts. 10 to 21, inc., the characteristics and suitability of all methods of surface and sub-surface drainage, and all types of foundations are discussed.

Broken Stone Foundations. Usually bituminous macadam pavements are constructed on broken stone foundations similar to the types described in Art. 10 in connection with methods of construction and in the various specifications contained in Art. 11.

Ohio State Highway Dept. Practice by Sharp (46). "On account of the greatly increased loads now (1917) being carried over improved roads, it is thought best that the foundation course be 5 in at the center and 4 in at the outsides. If a thicker course than this is required, it will be necessary to lay the foundation in two courses since it is not practicable to attempt to fill a course of greater thickness than this. Rolling should begin with the outside driver covering equal parts of the metal and shoulder. When the shoulders and sides of the metal are thoroly rolled, the rolling should progress gradually toward the center from each side until the entire course has been thoroly keyed and the interstices of the metal reduced to a minimum and all settlement has ceased. All low places developed during the rolling should be loosened, reshaped with suitable material and again consolidated by rolling. During the process of rolling one experienced in this kind of work can by careful attention rearrange the metal in the sur-

face to the extent of eliminating much of the unevenness and wavy surface conditions. Screenings that pass a ¾-in opening and not more than 40% passing a ¼-in opening, should be applied during the finishing process of dry rolling in such an amount as will completely fill the interstices. The screenings should not under any circumstances be dumped upon the surface of the stone, but should be cast thinly with a spreading motion of the shovel from piles at the roadside. If men are not experienced in the knack of whipping the screenings from the end of the shovels, during the process of filling, it is likely that the surface will be bridged in places by the screenings and complete filling not secured. It is very important that this be guarded against and the work be done under supervision of some one with an understanding of the proper method of carrying on this part of the work. The rolling should continue while the screenings are being spread so that the jarring effect of the roller will aid in settling them to the bottom. The roller should pass over the entire surface of the road after each application of screenings. In all probability, as the course is being compacted, it will be necessary to sweep the surface with a rattan or steel broom in order to effect a uniform distribution of the screenings and completely fill all voids. No excess of screenings should be used before applying water. Sufficient water should be applied to insure a dense surface and completely fill all interstices, the rolling to continue and screenings added until the metal ceases to sink under or move in front of the roller."

Cement-Concrete Foundations. In cases where traffic conditions require rigid foundations or where materials satisfactory for cement-concrete may be secured at a much lower cost than broken stone, cement-concrete foundations have been used and have been found to be satisfactory and economical. The more general use of cement-concrete foundations is advisable on trunk or other highways where traffic is liable to increase rapidly, both in amount and weight. When it is necessary to construct a more durable type of wearing course than bituminous macadam, the cement-concrete foundation previously constructed proves a valuable asset and allows reconstruction to be accomplished economically provided that proper foresight was exercised in placing the surface of the cement-concrete foundation at such an elevation as will permit the construction of other forms of pavements thereon. This remark applies particularly to curbed roadways in municipalities.

For a discussion of the relative advantages and cost of using broken stone and cement-concrete foundations see Art. 10, Method E and (22).

Conclusions of Third Int. Road Cong., London, 1913 (52). "Confirming the conclusions adopted in 1910 by the Second Congress, which called attention to the advantages of a dry foundation and a sound subsoil, the Congress especially insists upon the great importance of efficient foundations in the case of road crusts bound with bituminous binders for the following reasons:

1. The road crust being expensive, it is important to give it a base which will increase its life.

2. As the weight, speed and intensity of the traffic continually tend to increase on roads considered worthy of such a crust, it is best to provide a foundation which has been so constructed as to secure for the crust the best possible conditions of resistance to wear.

Conclusions of Spec. Com. Mat. Road Cons., Am. Soc. C. E. (16e). "The use of any form of a bituminous pavement or bituminous surface does not preclude the necessity for the construction of a well-drained, thoroly compacted, and adequate foundation. In fact, such improvement of the highway frequently attracts heavier traffic, and thus increases the stresses on the subgrade."

Conclusions of Ill. Highway Comm. (40a). "The results of the experience so far gained seem to show the necessity in this form of construction for as stable a foundation course as possible, and that probably the best method would be to lay the first course of the road as water-bound macadam, applying the bituminous top about 3 in thick the following season when the foundation course had become thoroly well compacted."

MATERIALS

5. Non-Bituminous Materials

Physical Qualities. In selecting and specifying rock and slag to be used in the construction of bituminous macadam pavements, toughness, resistance to abrasion, shape, and character and cleanliness of surface should be carefully considered.

Toughness and Resistance to Abrasion. See Sect. 11, Arts. 4 and 5. The weight to be given to these properties depends primarily upon the traffic to which the pavement will be subjected and the details of the method of construction adopted. For example, for many highways serving as feeders to state trunk routes, a rock having a toughness of not less than 6 and an abrasion loss of not more than 6% would prove economical and satisfactory; but if used on state trunk highways subjected to horse-drawn or motor-trucks, rock having a toughness of not less than 13 and an abrasion loss of not more than 3.5% should be employed. In cases where rock with suitable toughness and wearing quality is not locally available, satisfactory results may be obtained by importing the broken stone for the surface of the pavement and using local rock for the lower part of the crust.

Shape. In order that road metal should interlock during compaction and thus provide a stable wearing course, a proper angularity is an important prerequisite. The provision, often found in specifications, that broken stone should be cubical in shape is intended to cover this desirable quality of road metal. Cubes of rock or slag are not obtainable in practice, but the road metal meeting such a specification should not contain over 5% of particles having small acute angles, nor should the product contain slivers. Road metal with long acute angles and slivers is liable to rapidly fracture and crush under truck traffic.

Character of Surface. Road metal which has a rough or coarse grain or pitted surface is preferable to material with smooth or glassy surfaces as the bituminous cement adheres more satisfactorily to the former than to the latter.

Cleanliness is an essential quality of road metal for the wearing course of bituminous macadam pavements. Many failures have occurred from the use of dirty stone. It is difficult and usually impossible to secure a good adhesion of the bituminous cement to road metal which is not clean.

The Sizes of broken stone and slag used in bituminous macadam pavements vary primarily with the method of construction employed and the qualities of toughness and resistance to wear which the road metal possesses. As explained in Art. 10, covering methods of construction, and as illustrated by specifications contained in Arts. 6 and 11, the products used for wearing courses vary from one having road metal passing 1¼-in and retained on a ½-in screen to one in which the particles pass a 4½-in and are retained on a 3-in screen. The proper kind and size of material to be used as a filler will depend primarily upon the product used for the body of the wearing courses. For filler used in different methods, see Arts. 10 and 11.

From the standpoint of physical qualities, a safe rule is to increase the size of road metal as the toughness decreases or the loss by abrasion increases.

In using products, the particles of which are about the same size, special care must be taken in filling the voids of the wearing course in order that no rocking of the stone occurs. With hard, tough rocks there is more danger

of failure from this cause than when rocks or slags low in toughness and with a high loss on abrasion are used. The use of the trap rock product, the analysis of which follows, was the principal cause of one failure: Passing 1½-in screen, 37.5%; passing 1¼-in screen, 59.5%; passing 1-in screen, and retained on ½-in screen, 3.0%.

Massachusetts Practice Relative to Sizes and Qualities of Stone (31). "The size of stone in the top course is regarded as a matter of vital importance in the construction of a road by the penetration method. The Mass. Highway Comm. employs stone ranging from 1½ to 2½ in in size. The large stone, it has been found, binds together more firmly than smaller stone and consequently is subject to less wear from the grinding of one fragment against another in the body of the pavement due to the passage of vehicles over the road surface. Small-sized stone tends to loosen quickly under this grinding action, and if the bituminous binder loses its life and is not speedily renewed the road quickly goes to pieces. With stone of large size no such result may be expected. It is true that with the larger stone the voids are greater and consequently a larger amount of bituminous material must be used to fill them, the excess being generally about ⅜ gal per in depth of top course for the large stone type of construction. Thus a small stone pavement with tar as a binder and a 2-in top course would cost about 6 cents less a square yard than the large stone type of pavement. In spite of this slight increase in cost, the use of the large stone is believed to be amply justified. With small stone it is practically impossible to secure any great depth of penetration with a single application of bituminous material. It becomes necessary, therefore, if small size stone is used, to build the top course in several layers and apply the binder to each, obviously a more costly procedure than the distribution of the binder in a single operation as is feasible when large stone is used.

"As to the quality of the stone in the top course, this depends to a large extent upon the character of the traffic to be handled. For very heavy teaming the Mass. Comm. believes that the best results can be secured with trap rock and a high grade asphalt. With a tar binder, instead of asphalt, a softer grade of rock is permissible, for the tars deteriorate more quickly than do the asphalts. Asphalts are preferred because of their greater cementing value and their higher resistance to disintegration by moisture."

Ill. Highway Comm. Conclusions Relative to Sizes and Quality of Stone (40a). "Durable material in the bituminous top should be used, and where, under the conditions that exist in Illinois, limestone alone is available, the material used for filling the voids and dressing the surface of the bituminous layers as they are applied, should be of washed gravel and torpedo sand. The particles of the gravel are made up for the most part of silicious material, which is the hardest material available, but where the rock of which the road is made is tough and hard, then rock chips could be substituted. The size of stone in the bituminous layer should range from 2½ to ¾ in where limestone is used. When trap rock or other equally hard material is available, stone should not exceed 2 in in size; the chips for filling the stone not to exceed ¾ in and the grit for the top dressing not to exceed ¼ in, and all of the materials to be free from dust."

Conclusions on Sizes of Stone for Filling Voids by Hubbard (38a). "Immediately after application of the bituminous material a light layer of clean, dry, broken stone, which will pass a ⅝-in but be retained upon a ¼-in screen, should be evenly spread over the road and at once rolled into the surface voids. Frequently a larger size of broken stone is used for this purpose, that is, stone as large as ¾-in diameter. This is bad practice for the reason that if the top course has been properly constructed and rolled the surface voids are not sufficiently large to accommodate ¾-in stone. Under the action of the roller they will therefore either be crushed or if of very hard rock will project into the finished surface. In the first case so much dust is produced as to prevent proper penetration and adhesion of the seal coat of bituminous material which is afterwards applied. In the second case the stone is of such size as to be more or less readily caught and pried out by traffic, especially horse-drawn traffic. On the other hand, if the stone above recommended is used, the surface voids of the properly compacted top course may be evenly filled and a minimum amount of crushing will be produced by the roller. In addition, satisfactory surface consolidation is more readily obtained as there are no scattered high points for the roller to pass over and the weight of the roller is thus more evenly distributed over the entire surface."

6. Specifications for Non-Bituminous Materials

The most satisfactory form of specifications covering sizes of broken stone is that recommended by Com. D-4, Standard Tests for Road Materials, Am. Soc. Test. Mat. and the Spec. Com. Mat. Road Cons., Am. Soc. C. E. (see Art 7, Sect. 11).

The Form of Specification for broken stone for bituminous macadam, as adopted at the first conference of State Highway Testing Engineers and Chemists held at the U. S. O. P. R. in Feb., 1917 (53 b) was as follows:

"**General.** The broken stone shall consist of angular fragments of (insert types of allowable), of uniform quality thruout, free from thin or elongated pieces, soft or disintegrated stone, dirt, or other objectionable matter occurring either free or as a coating on the stone.

"**Physical Properties.** The stone shall meet the following requirements:

Percent of wear..........................not more than..........
(or French coefficient).....................not less than..........
*Toughness..............................not less than..........
*Hardness...............................not less than..........
*Absorption.............................not more than..........

"**Chips or No. . . . Stone.** That portion of the product of the crusher which, when tested by means of laboratory screens, will meet the following requirements:

Passing..........inch screen................................100%.
Total passing..........inch screen............% to............%.
Retained on..........inch screen............................100%.

"**Top Course or No. . . . Stone.** That portion of the product of the crusher which, when tested by means of laboratory screens, will meet the following requirements:

Passing..........inch screen................................100%.
Total passing..........inch screen.............% to ....%.
Retained on..........inch screen............................100%.

"**Bottom Course or No. . . . Stone.** That portion of the product of the crusher which, when tested by means of laboratory screens, will meet the following requirement:

Passing..........inch screen................................100%.
Total passing..........inch screen.............% to...........%.
Retained on..........inch screen............................100%."

Am. Soc. Mun. Imp. 1917 Specifications for Broken Stone are as follows:

"**Quality of Broken Stone.** All broken stone shall be clean, rough surfaced and sharp angled, of compact texture and uniform grain.

"**Tests for Broken Stone.** The broken stone shall be subjected to abrasion tests and toughness tests conducted by the Engineer in accordance with methods adopted by the Am. Soc. Test. Mat., Aug. 15, 1908. The broken stone used for the construction of the first and second courses shall show a French coefficient of wear of not less than 7.0 and its toughness shall be not less than 6.0. The broken stone used for the construction of the third course and for the first and second applications of No. 1 broken stone shall show a French coefficient of wear of not less than 11.0 and its toughness shall not be less than 13.0."

Sizes of Broken Stone. For specifications covering the sizes to which reference is made in the specifications for construction contained in Art. 11, see Art. 7, Sect. 11.

U. S. O. P. R. 1918 Specifications for Broken Stone are as follows:

"**General.** The broken stone shall consist of angular fragments of rock excluding schist, shale and slate, of uniform quality thruout, free from thin or elongated pieces, soft or disintegrated stone, dirt or other objectionable matter occurring either free or as a coating on the stone.

"**Physical Properties.** The stone shall meet the following requirements: French coefficient of wear, not less than 7.

"**Chips.** That portion of the product of the crusher which, when tested by means of laboratory screens, will meet the following requirements:

---

*Tests recommended by the conference which it may be desirable to omit in some instances.

	Percent
Passing 1-in screen, not less than	95
Retained on ¼-in screen, not less than	85

"Coarse Stone. That portion of the product of the crusher which, when tested by means of laboratory screens, will meet the following requirements:

	Percent
Passing 2-in screen, not less than	95
Total passing 1½-in screen	25 to 75
Retained on 1-in screen, not less than	85

"Methods of Testing. Tests of the physical properties of the rock and of the sizes of broken stone products shall be made in accordance with the following methods:

1. French Coefficient of Wear: U. S. Dept. Agr. Bul. 347, p. 5.
2. Size: U. S. Dept. Agr. Bul. 555, p. 32.

"Notes: This specification covers stone to be used in the construction of a bituminous broken stone wearing course in which the bituminous material is applied by the penetration method. The maximum size of 2 in specified for the wearing course is on the basis of a course 2½ to 3 in in thickness after consolidation. The chips should be used to fill the surface voids after the first application of bituminous material has been made and also as a cover for the second application or seal coat."

Ohio State Highway Dept. Specifications for Road Metal are as follows (46):

"Limestone for Foundation Course. The broken stone shall be clean, sound, durable and of uniform quality. It shall contain not less than 55% of calcium carbonate except in the case of a dolomitic limestone, when the sum of the percentage of calcium carbonate and magnesium carbonate shall be not less than 60%. The stone shall show in the abrasion test a loss of not more than 12%, a factor of hardness of not less than 10 and a toughness of not less than 4.

"Slag for Foundation Course. The slag shall be clean, sound, durable and of uniform quality and shall contain not less than 30% of silica and not more than 45% of calcium oxide and not more than 1.5% of sulphur. The slag shall show in the abrasion test a loss of not more than 12%, a factor of hardness of not less than 14 and a toughness of not less than 5.

"Sandstone for Foundation Course. The sandstone shall be clean, sound and durable and of uniform quality. The stone shall show in the abrasion test a loss of not more than 25% and a toughness of not less than 3.

"Limestone for Wearing Course. The stone shall be clean, sound, durable, of uniform quality and free from thin, flat and shaley pieces. It shall contain not less than 65% of calcium carbonate, except in cases of dolomitic limestone, when the sum of the percentage of calcium carbonate and magnesium carbonate shall be not less than 70%. The stone should show in the abrasion test a loss of not more than 6%, a factor of hardness of not less than 15 and a toughness of not less than 6.

"Slag for Wearing Course. The broken slag shall be clean, sound, durable and of uniform quality and shall contain not less than 32% of silica and not more than 25% of calcium oxide and not more than 1½% of sulphur. Slag shall show in the abrasion test a loss of not more than 10%, a hardness of not less than 16 and a toughness of not less than 5. Slag aggregates shall weigh not less than 75 lb per cu ft."

Oakland, Cal., Specifications for Broken Stone of the Wearing Course. For method of use, see Art. 11, Method G.

"Broken Stone for the Top Course shall be sound, hard, tough and have irregular cleavage. It shall be free from lumps of clay, loam, or other foreign materials, and shall have clean, fresh surfaces. It shall be of such size that all will pass a screen having circular openings 2½ in in diameter; at least 90% will pass a screen having circular openings 2 in in diameter, and at least 85% will be retained on a screen having circular openings ¾ in in diameter, and at least 75% shall be the run of the crusher between said 2-in and 1-in sizes. Not more than 1% may pass a screen having 1/16-in circular openings. The stone shall all be of such quality that it will not lose by abrasion more than 28% of its original weight in the rattler test.

"Screenings for the Top Course shall be of such size that all will pass a screen having circular openings ¾ in in diameter and at least 95% be retained on a screen having 1/16-in circular openings, and shall be the run of the crusher between said

sizes. Screenings shall be broken from rock of the quality herein specified for the top course, excepting that all screenings used after the last oiling shall be from rock that will lose not more than 20% of its original weight in the rattler test prescribed for top-course broken stone.

"Rattler Test. The aforesaid rattler tests shall be conducted in the rattler used for this purpose in the laboratory maintained by the Street Department of the City of Oakland. Samples for this test shall be selected by shoveling broken stone from the street, screening as hereinafter described, and revolving 100 lb of the broken stone in the rattler at a rate of not less than 28 nor more than 30 rev per min. For the base course the sample shall be shaken on two hand screens having circular openings respectively 4 in and 1½ in in diameter until 100 lb is obtained that passes the larger screen and is retained on the smaller; and the revolutions of the rattler shall continue until it has revolved 1500 times. For the top course the sample shall be shaken on two hand screens having circular openings respectively 2 in and 1 in in diameter until 100 lb is obtained that passes the larger screen and is retained on the smaller; and the revolutions of the rattler shall continue until it has revolved 5000 times."

7. Bituminous Materials

The bituminous materials which have been used successfully in the construction of bituminous pavements built by penetration methods, include asphalts, refined water-gas tars, refined coal-gas tars, combinations of refined tars, and combinations of refined tars and asphalts.

Conclusions on Suitable Bituminous Materials by Hubbard (38a). "The bituminous material used in the construction of a bituminous macadam pavement is the same for both applications. It may be a comparatively soft petroleum asphalt, fluxed native asphalt, or a heavy refined tar. The function of a bituminous cement in the bituminous macadam is not so much to hold the wearing course up as to keep the large stone fragments down under traffic. The keyed stone itself has sufficient bearing quality or mechanical stability to carry traffic and it is therefore possible to use a much softer cement than for the same thickness of fine aggregates which lack inherent mechanical stability. The cements most advantageously used are, however, much nearer solid consistency than those which it is possible to use in the construction of a bituminous carpet alone. In general, it is advisable to use a softer tar product than petroleum or asphalt product."

Forms of Reports for bituminous materials, as follows, were adopted at the first conference of State Highway Testing Engineers and Chemists, held at the U. S. O. P. R. in Feb., 1917 (53b).

8. Specifications for Bituminous Materials

Closed, Blanket and Alternate Type Specifications for bituminous materials are fully discussed in Sect. 12, Arts. 49 and 50. In this article, the specifications of the Am. Soc. Mun. Imp. well illustrate the alternate type specifications. The Penn. State Highway Dept. specification for asphalt

cement is a modification of a typical blanket specification, as alternate requirements for different kinds of asphalt cement are given in the sections covering penetration and solubility in carbon disulphide.

The Form of Specification for Asphalt Cement for bituminous macadam pavements adopted at the first conference of State Highway Engineers and Chemists held at the U. S. O. P. R. in Feb., 1917 (53b), was as follows:

"General. The asphalt cement shall be homogeneous, free from water, and shall not foam when heated to ....° C (........° F).

"Physical and Chemical Properties. It shall meet the following requirements:

1. Specific gravity 25°/25° C (77°/77° F)..................to....................
2. Flash point.......................not less than............° C (.........° F).
3. Melting point............° C (............° F) to ....° C (........° F).
   or Ductility at......° C (......° F), not less than ....cm, or .... cm to..........cm.
4. Penetration at 25° C* (77° F), 100 g, 5 sec,................to................
5. Loss at 163° C (325° F), 5 hr....................not over.................%,
   Penetration of residue at 25° C (77° F), 100 g, 5 sec.........not less than.......
6. Total bitumen, soluble in carbon disulphide, not less than.....................%.
   a. Organic matter insoluble....................not over.................%.
   b. Inorganic matter insoluble......not over........%, or......% to.....%.

"Method of Testing. Tests of the physical and chemical properties of the asphalt cement shall be made in accordance with the methods described, or referred to on page .... of these specifications, test Nos............

"NOTES. 1. In some instances it may be considered desirable to include an 86° B naphtha solubility clause, in which case the wording should be: Percent of total bitumen insoluble in 86° B naphtha............% to ....%.

2. In some instances it may be considered desirable to include a fixed carbon test, in which case the wording should be: Fixed carbon............% to...........%.

3. In certain cases the inclusion of all the tests listed or noted may not be desirable, but it is necessary to use certain combinations of the tests in order to secure a material suitable for a specified purpose."

Am. Soc. Mun. Imp. 1917 Specifications for Asphalt Cements and Refined Tars for Bituminous Macadam Pavements:

"Previous Service. The Contractor will be required to show, to the satisfaction of the Engineer, that the Company manufacturing the asphalt cement or refined tar he proposes to use under a given specification has, for a period of at least 2 years, manufactured asphalt cement or refined tar in a thoroly equipped plant, and that asphalt cement or refined tar manufactured of bituminous material obtained from a similar source to that which he proposes to use, shall have been in continuous and successful use in bituminous pavements constructed by the mixing method or in bituminous macadam pavements for a period of at least 2 years previous to the date of the letting in which his proposal was submitted.

"Asphalt Cement A optional with asphalt cements B, C, D and refined tars E and F.

1. Asphalt cement A shall be homogeneous, free from water and shall not foam when heated to 177° C (350° F).

2. It shall show a flash point of not less than 205° C (400° F) when tested in the New York State Board of Health Closed Oil Tester.

3. Its specific gravity, at a temperature of 25° C (77° F), shall be not less than 0.960 nor more than 1.000.

4. When tested with a standard No. 2 needle by means of a standard penetrometer, it shall show penetrations within the following limits for the conditions stated, the penetrations being expressed in hundredths of a centimeter, 100 g load, 5 sec, at 25° C (77° F), from 100 to 120; 200 g load, 1 min, at 4° C (39° F), not less than 50.

---

*In some instances it may be desirable to insert a requirement for penetration at the temperatures of 0° C (32° F) and 46.1° C (115° F) in which cases the clauses would read as follows:

Penetration at 0° C (32° F), 200 g, 60 sec......to...... or not less than ....
Penetration at 46.1° C (115° F), 50 g, 5 sec, ... to ...... or not over..........

5. Its melting point as determined by the cube method shall be not less than 60° C (140° F).

6. When 50 g of the material is maintained at a uniform temperature of 163° C (325° F) for 5 hr in an open cylindrical tin dish 5½ cm (about 2¼ in) in diameter, with vertical sides measuring approximately 3½ cm (about 1½ in) in depth, the loss in weight shall not exceed 2% of the original weight of the sample. The penetration of the residue, when tested as described in Clause 4 with a standard No. 2 needle under a load of 100 g, for 5 sec at 25° C (77° F) shall be not less than one-half the penetration of the original material tested under the same condition.

7. Its bitumen as determined by its solubility in chemically pure carbon disulphide at room temperature, shall be not less than 99.5%.

8. It shall be soluble in chemically pure carbon tetrachloride at room temperature, to the extent of not less than 99.5% of its bitumen as determined by Clause 7.

9. It shall be soluble in 86° to 88° B paraffin naphtha, of which at least 85% distills between 35° and 65° C (95° and 149° F), to the extent of not less than 75% nor more than 85% of its bitumen as determined by Clause 7.

10. It shall yield not less than 8% nor more than 12% of fixed carbon.

"Asphalt Cement B optional with asphalt cements A, C, D, and refined tars E and F.

1. Asphalt cement B shall be homogeneous, free from water and shall not foam when heated to 177° C (350° F).

2. It shall show a flash point of not less than 205° C (400° F) when tested in the New York State Board of Health Closed Oil Tester.

3. Its specific gravity, at a temperature of 25° C (77° F), shall be not less than 1.000 nor more than 1.080.

4. When tested with a standard No. 2 needle by means of a standard penetrometer, it shall show penetrations within the following limits for the conditions stated, the penetrations being expressed in hundredths of a centimeter, 100 g load, 5 sec, at 25° C (77° F), from 90 to 110; 200 g load, 1 min, at 4° C (39° F), not less than 15.

5. Its melting point as determined by the cube method shall be not less than 30° C (86° F).

6. When 50 g of the material is maintained at a uniform temperature of 163° C (325° F) for 5 hr in an open cylindrical tin dish 5½ cm (about 2¼ in) in diameter, with vertical sides measuring approximately 3½ cm (about 1½ in) in depth, the loss in weight shall not exceed 2.0% of the original weight of the sample. The penetration of the residue, when tested as described in Clause 4 with a standard No. 2 needle under a load of 100 g for 5 sec at 25° C (77° F), shall be not less than one-half the penetration of the original material tested under the same conditions.

7. Its bitumen, as determined by its solubility in chemically pure carbon disulphide at room temperature, shall be not less than 99.5%.

8. It shall be soluble in chemically pure carbon tetrachloride at room temperature, to the extent of not less than 99.5% of its bitumen as determined by Clause 7.

9. It shall be soluble in 86° to 88° B paraffin naphtha, of which at least 85% distills between 35° and 65° C (95° and 149° F), to the extent of not less than 75% nor more than 85% of its bitumen as determined by Clause 7.

10. It shall yield not less than 9% nor more than 13% of fixed carbon.

"Asphalt Cement C optional with asphalt cements A, B, D, and refined tars E and F.

1. Asphalt cement C shall be homogeneous, free from water and shall not foam when heated to 177° C (350° F).

2. It shall show a flash point of not less than 205° C (400° F) when tested in the New York State Board of Health Closed Oil Tester.

3. Its specific gravity, at a temperature of 25° C (77° F) shall be not less than 1.025 nor more than 1.045.

4. When tested with a standard No. 2 needle by means of a standard penetrometer, it shall show penetrations within the following limits for the conditions stated, the penetrations being expressed in hundredths of a centimeter: 100 g load, 5 sec, at 25° C (77° F), from 110 to 130; 200 g load, 1 min, at 4° C (39° F) not less than 30.

5. Its melting point as determined by the cube method shall be not less than 40° C (104° F).

6. When 50 g of the material is maintained at a uniform temperature of 163° C (325° F) for 5 hr in an open cylindrical tin dish 5½ cm (about 2¼ in) in diameter, with

vertical sides measuring approximately 3½ cm (about 1½ in) in depth, the loss in weight shall not exceed 2% of the original weight of the sample. The penetration of the residue, when tested as described in Clause 4 with a standard No. 2 needle under a load of 100 g for 5 sec at 25° C (77° F), shall be not less than one-half the penetration of the original material tested under the same conditions.

7. Its bitumen, as determined by its solubility in chemically pure carbon disulphide at room temperature, shall be not less than 99.5%.

8. It shall be soluble in chemically pure carbon tetrachloride at room temperature, to the extent of not less than 99.5% of its bitumen as determined by Clause 7.

9. It shall be soluble in 86° to 88° B paraffin naphtha, of which at least 85% distills between 35° and 65° C (95° and 149° F) to the extent of not less than 70% nor more than 80% of its bitumen as determined by Clause 7.

10. It shall yield not less than 12% nor more than 17% of fixed carbon.

"Asphalt Cement D optional with asphalt cements A, B, C, and refined tars E and F

1. Asphalt cement D shall be homogeneous, free from water and shall not foam when heated to 177° C (350° F).

2. It shall show a flash point of not less than 163° C (325° F) when tested in the New York State Board of Health Closed Oil Tester.

3. Its specific gravity, at a temperature of 25° C (77° F) shall be not less than 1.035 nor more than 1.060.

4. When tested with a standard No. 2 needle by means of a standard penetrometer, it shall show penetrations within the following limits for the conditions stated, the penetrations being expressed in hundredths of a centimeter: 100 g load, 5 sec, at 25° C (77° F), from 130 to 160; 200 g load, 1 min at 4° C (39° F), not less than 30.

5. When tested by means of the New York Testing Laboratory Float Apparatus the float shall not sink in water maintained at 66° C (150° F) in less than 120 sec nor more than 180 sec.

6. When 50 g of the material is maintained at a uniform temperature of 163° C (325° F) for 5 hr in an open cylindrical tin dish 5½ cm (about 2¼ in) in diameter, with vertical sides measuring approximately 3½ cm (about 1½ in) in depth, the loss in weight shall not exceed 3% of the original weight of the sample. The penetration of the residue, when tested as described in Clause 4 with a standard No. 2 needle under a load of 100 g, for 5 sec at 25° C (77° F), shall be not less than one-half the penetration of the original material tested under the same conditions.

7. Its bitumen, as determined by its solubility in chemically pure carbon disulphide at room temperature, shall be not less than 94% nor more than 98%.

8. It shall be soluble in chemically pure carbon tetrachloride at room temperature to the extent of not less than 98.5% of its bitumen as determined by Clause 7.

9. It shall be soluble in 86° to 88° B paraffin naphtha, of which at least 85% distills between 35° and 65° C (95° and 149° F) to the extent of not less than 75% nor more than 85% of its bitumen as determined by Clause 7.

10. It shall yield not less than 11% nor more than 14% of fixed carbon.

11. Upon ignition it shall yield not less than 1% nor more than 3% of ash.

" Refined Tar E optional with asphalt cements A, B, C, D, and refined tar F.

1. Refined tar E shall be homogeneous, free from water, and shall not foam when heated to 121° C (250° F).

2. Its specific gravity at a temperature of 25° C (77° F) shall be not less than 1.150 nor more than 1.200.

3. When tested by means of the New York Testing Laboratory Float Apparatus, the float shall not sink in water maintained at 50° C (122° F) in less than 120 nor more than 150 sec.

4. Its bitumen as determined by its solubility in chemically pure carbon disulphide at room temperature, shall be not less than 95%, and it shall show not more than 0.2% ash upon ignition of the material insoluble in carbon disulphide.

5. When distilled according to the tentative method recommended by Com. D-4, Am. Soc. Test. Mat. in 1911, it shall yield not more than 0.5% distillate at a temperature lower than 170° C (338° F); not more than 12% shall distill below 270° C (518° F) and not more than 25% shall disdill below 300° C (572° F).

6. The total distillate from the test made in accordance with Clause 5 shall have a specific gravity at a temperature of 25° C (77° F) of not less than 0.980 nor more than 1.020.

7. The melting point, as determined in water by the cube method, of the pitch residue remaining after distillation to 300° C (572° F) in accordance with the test described in Clause 5, shall be not more than 75° C (167° F).

"Refined Tar F optional with asphalt cements A, B, C, D, and refined tar E.

1. Refined tar F shall be homogeneous, free from water, and shall not foam when heated to 121° C (250° F).

2. Its specific gravity at a temperature of 25° C (77° F) shall be not less than 1.180 nor more than 1.300.

3. When tested by means of the New York Testing Laboratory Float Apparatus, the float shall not sink in water maintained at 50° C (122° F) in less than 150 nor more than 180 sec.

4. Its bitumen as determined by its solubility in chemically pure carbon disulphide at room temperature, shall be not less than 80% nor more than 95%, and it shall show not more than 0.2% ash upon ignition of the material insoluble in carbon disulphide.

5. When distilled according to the tentative method recommended by Com. D-4 of the Am. Soc. Test. Mat. in 1911, it shall yield not more than 0.5% distillate at a temperature lower than 170° C (338° F); not more than 10% shall distill below 270° C (518° F), and not more than 20% shall distill below 300° C (572° F).

6. The total distillate from the test made in accordance with Clause 5 shall have a specific gravity at a temperature of 25° C (77° F) of not less than 1.020.

7. The melting point, as determined in water by the cube method, of the pitch residue remaining after distillation to 300° C (572° F) in accordance with the test described in Clause 5, shall be not more than 75° C (167° F).

NOTES: Asphalt cements can be manufactured from Gilsonite and asphaltic oil to meet specification A; from Texas and California asphaltic oils to meet specification B; from Mexican asphaltic oils to meet specification C; from asphaltic material from Bermudez to meet specification D. Refined tars can be manufactured from water-gas tar to meet specification E; and from coal tar or a combination of coal tar and water-gas tar to meet specification F.

"Delivery. The asphalt cement or refined tar shall be delivered in suitable containers, far enough in advance of its use in the work to permit the necessary tests to be made. Each container shall be plainly labelled with the trade name of the asphalt cement or refined tar, name of manufacturer, gross weight and net weight. Each shipment and each carload shall be kept separate.

"Bills of Lading. The contractor shall furnish the Engineer on or before the arrival of each shipment at or near the site of the work, bills of lading, or correct copies thereof, which shall state the trade name of the asphalt cement or refined tar, and the name and address of the company manufacturing and supplying it.

"Samples will be taken by the Engineer from each carload of asphalt cement or refined tar when delivered at the work, unless satisfactory arrangements can be made for sampling before shipment. Such samples shall be analyzed by the Engineer to assure the delivery of an asphalt cement or refined tar of the specified quality and to determine, for purpose of payment, the quantity of bitumen.

"Work Included. Under this item the contractor shall furnish and deliver on the work at such points as directed an asphalt cement or refined tar which conforms with the specifications of any one of the asphalt cements or refined tars given above.

"Measurement and Payment. The quantity of bitumen in the asphalt cement or refined tar, to be paid for under this item, shall be the number of tons, determined in accordance with the paragraph headed SAMPLES, contained in the asphalt cement or refined tar placed in the pavement in accordance with the specifications and requirements, or used as directed for other purposes. The percentage of bitumen determined by an average of the analyses of the acceptable samples taken by the Engineer during a given month shall be used as the basis for payment for the asphalt cement or refined tar used during that month. Asphalt cement or refined tar that is wasted shall not be included in the measurement under this item. The price stipulated in this item shall include the cost of furnishing, hauling and delivering the asphalt cement or refined tar at the work, and all expenses incidental thereto."

Ohio State Highway Dept. Specifications for Asphalt Cement (46) are as follows:

"1. It shall be homogeneous in character.

cement is a modification of a typical blanket specification, as alternate requirements for different kinds of asphalt cement are given in the sections covering penetration and solubility in carbon disulphide.

The Form of Specification for Asphalt Cement for bituminous macadam pavements adopted at the first conference of State Highway Engineers and Chemists held at the U. S. O. P. R. in Feb., 1917 (53b), was as follows:

"General. The asphalt cement shall be homogeneous, free from water, and shall not foam when heated to ....° C (........° F).

"Physical and Chemical Properties. It shall meet the following requirements:

1. Specific gravity 25°/25° C (77°/77° F)................to..................
2. Flash point.......................not less than............° C (.........° F).
3. Melting point............° C (............° F) to ....° C (........° F), or Ductility at......° C (......° F), not less than ....cm, or .... cm to.........cm.
4. Penetration at 25° C* (77° F), 100 g, 5 sec,................to...............
5. Loss at 163° C (325° F), 5 hr...................not over................%, Penetration of residue at 25° C (77° F), 100 g, 5 sec.........not less than........
6. Total bitumen, soluble in carbon disulphide, not less than...................%.
   a. Organic matter insoluble..................not over.................%.
   b. Inorganic matter insoluble......not over........%, or......% to......%.

"Method of Testing. Tests of the physical and chemical properties of the asphalt cement shall be made in accordance with the methods described, or referred to on page .... of these specifications, test Nos............

"NOTES. 1. In some instances it may be considered desirable to include an 86° B naphtha solubility clause, in which case the wording should be: Percent of total bitumen insoluble in 86° B naphtha............% to ....%.

2. In some instances it may be considered desirable to include a fixed carbon test, in which case the wording should be: Fixed carbon............% to...........%.

3. In certain cases the inclusion of all the tests listed or noted may not be desirable, but it is necessary to use certain combinations of the tests in order to secure a material suitable for a specified purpose."

Am. Soc. Mun. Imp. 1917 Specifications for Asphalt Cements and Refined Tars for Bituminous Macadam Pavements:

"Previous Service. The Contractor will be required to show, to the satisfaction of the Engineer, that the Company manufacturing the asphalt cement or refined tar he proposes to use under a given specification has, for a period of at least 2 years, manufactured asphalt cement or refined tar in a thoroly equipped plant, and that asphalt cement or refined tar manufactured of bituminous material obtained from a similar source to that which he proposes to use, shall have been in continuous and successful use in bituminous pavements constructed by the mixing method or in bituminous macadam pavements for a period of at least 2 years previous to the date of the letting in which his proposal was submitted.

"Asphalt Cement A optional with asphalt cements B, C, D and refined tars E and F.

1. Asphalt cement A shall be homogeneous, free from water and shall not foam when heated to 177° C (350° F).

2. It shall show a flash point of not less than 205° C (400° F) when tested in the New York State Board of Health Closed Oil Tester.

3. Its specific gravity, at a temperature of 25° C (77° F), shall be not less than 0.960 nor more than 1.000.

4. When tested with a standard No. 2 needle by means of a standard penetrometer, it shall show penetrations within the following limits for the conditions stated, the penetrations being expressed in hundredths of a centimeter, 100 g load, 5 sec, at 25° C (77° F), from 100 to 120; 200 g load, 1 min, at 4° C (39° F), not less than 50.

---

*In some instances it may be desirable to insert a requirement for penetration at the temperatures of 0° C (32° F) and 46.1° C (115° F) in which cases the clauses would read as follows:

Penetration at 0° C (32° F), 200 g, 60 sec......to...... or not less than ....
Penetration at 46.1° C (115° F), 50 g, 5 sec, ... to ...... or not over..........

5. Its melting point as determined by the cube method shall be not less than 60° C (140° F).

6. When 50 g of the material is maintained at a uniform temperature of 163° C (325° F) for 5 hr in an open cylindrical tin dish 5½ cm (about 2¼ in) in diameter, with vertical sides measuring approximately 3½ cm (about 1½ in) in depth, the loss in weight shall not exceed 2% of the original weight of the sample. The penetration of the residue, when tested as described in Clause 4 with a standard No. 2 needle under a load of 100 g, for 5 sec at 25° C (77° F) shall be not less than one-half the penetration of the original material tested under the same condition.

7. Its bitumen as determined by its solubility in chemically pure carbon disulphide at room temperature, shall be not less than 99.5%.

8. It shall be soluble in chemically pure carbon tetrachloride at room temperature, to the extent of not less than 99.5% of its bitumen as determined by Clause 7.

9. It shall be soluble in 86° to 88° B paraffin naphtha, of which at least 85% distills between 35° and 65° C (95° and 149° F), to the extent of not less than 75% nor more than 85% of its bitumen as determined by Clause 7.

10. It shall yield not less than 8% nor more than 12% of fixed carbon.

"**Asphalt** Cement B optional with asphalt cements A, C, D, and refined tars E and F.

1. Asphalt cement B shall be homogeneous, free from water and shall not foam when heated to 177° C (350° F).

2. It shall show a flash point of not less than 205° C (400° F) when tested in the New York State Board of Health Closed Oil Tester.

3. Its specific gravity, at a temperature of 25° C (77° F), shall be not less than 1.000 nor more than 1.030.

4. When tested with a standard No. 2 needle by means of a standard penetrometer, it shall show penetrations within the following limits for the conditions stated, the penetrations being expressed in hundredths of a centimeter, 100 g load, 5 sec, at 25° C (77° F), from 90 to 110; 200 g load, 1 min, at 4° C (39° F), not less than 15.

5. Its melting point as determined by the cube method shall be not less than 30° C (86° F).

6. When 50 g of the material is maintained at a uniform temperature of 163° C (325° F) for 5 hr in an open cylindrical tin dish 5½ cm (about 2¼ in) in diameter, with vertical sides measuring approximately 3½ cm (about 1½ in) in depth, the loss in weight shall not exceed 2.0% of the original weight of the sample. The penetration of the residue, when tested as described in Clause 4 with a standard No. 2 needle under a load of 100 g for 5 sec at 25° C (77° F), shall be not less than one-half the penetration of the original material tested under the same conditions.

7. Its bitumen, as determined by its solubility in chemically pure carbon disulphide at room temperature, shall be not less than 99.5%.

8. It shall be soluble in chemically pure carbon tetrachloride at room temperature, to the extent of not less than 99.5% of its bitumen as determined by Clause 7.

9. It shall be soluble in 86° to 88° B paraffin naphtha, of which at least 85% distills between 35° and 65° C (95° and 149° F), to the extent of not less than 75% nor more than 85% of its bitumen as determined by Clause 7.

10. It shall yield not less than 9% nor more than 13% of fixed carbon.

"**Asphalt** Cement C optional with asphalt cements A, B, D, and refined tars E and F.

1. Asphalt cement C shall be homogeneous, free from water and shall not foam when heated to 177° C (350° F).

2. It shall show a flash point of not less than 205° C (400° F) when tested in the New York State Board of Health Closed Oil Tester.

3. Its specific gravity, at a temperature of 25° C (77° F) shall be not less than 1.025 nor more than 1.045.

4. When tested with a standard No. 2 needle by means of a standard penetrometer, it shall show penetrations within the following limits for the conditions stated, the penetrations being expressed in hundredths of a centimeter: 100 g load, 5 sec, at 25° C (77° F), from 110 to 130; 200 g load, 1 min, at 4° C (39° F) not less than 30.

5. Its melting point as determined by the cube method shall be not less than 40° C (104° F).

6. When 50 g of the material is maintained at a uniform temperature of 163° C (325° F) for 5 hr in an open cylindrical tin dish 5½ cm (about 2¼ in) in diameter, with

vertical sides measuring approximately 3⅓ cm (about 1⅓ in) in depth, the loss in weight shall not exceed 2% of the original weight of the sample. The penetration of the residue, when tested as described in Clause 4 with a standard No. 2 needle under a load of 100 g for 5 sec at 25° C (77° F), shall be not less than one-half the penetration of the original material tested under the same conditions.

7. Its bitumen, as determined by its solubility in chemically pure carbon disulphide at room temperature, shall be not less than 99.5%.

8. It shall be soluble in chemically pure carbon tetrachloride at room temperature, to the extent of not less than 99.5% of its bitumen as determned by Clause 7.

9. It shall be soluble in 86° to 88° B paraffin naphtha, of which at least 85% distills between 35° and 65° C (95° and 149° F) to the extent of not less than 70% nor more than 80% of its bitumen as determined by Clause 7.

10. It shall yield not less than 12% nor more than 17% of fixed carbon.

"Asphalt Cement D optional with asphalt cements A, B, C, and refined tars E and F.

1. Asphalt cement D shall be homogeneous, free from water and shall not foam when heated to 177° C (350° F).

2. It shall show a flash point of not less than 163° C (325° F) when tested in the New York State Board of Health Closed Oil Tester.

3. Its specific gravity, at a temperature of 25° C (77° F) shall be not less than 1.035 nor more than 1.060.

4. When tested with a standard No. 2 needle by means of a standard penetrometer, it shall show penetrations within the following limits for the conditions stated, the penetrations being expressed in hundredths of a centimeter: 100 g load, 5 sec, at 25° C (77° F), from 130 to 160; 200 g load, 1 min at 4° C (39° F), not less than 30.

5. When tested by means of the New York Testing Laboratory Float Apparatus the float shall not sink in water maintained at 66° C (150° F) in less than 120 sec nor more than 180 sec.

6. When 50 g of the material is maintained at a uniform temperature of 163° C (325° F) for 5 hr in an open cylindrical tin dish 5⅓ cm (about 2¼ in) in diameter, with vertical sides measuring approximately 3⅓ cm (about 1½ in) in depth, the loss in weight shall not exceed 3% of the original weight of the sample. The penetration of the residue, when tested as described in Clause 4 with a standard No. 2 needle under a load of 100 g, for 5 sec at 25° C (77° F), shall be not less than one-half the penetration of the original material tested under the same conditions.

7. Its bitumen, as determined by its solubility in chemically pure carbon disulphide at room temperature, shall be not less than 94% nor more than 98%.

8. It shall be soluble in chemically pure carbon tetrachloride at room temperature to the extent of not less than 98.5% of its bitumen as determined by Clause 7.

9. It shall be soluble in 86° to 88° B paraffin naphtha, of which at least 85% distills between 35° and 65° C (95° and 149° F) to the extent of not less than 75% nor more than 85% of its bitumen as determined by Clause 7.

10. It shall yield not less than 11% nor more than 14% of fixed carbon.

11. Upon ignition it shall yield not less than 1% nor more than 3% of ash.

"Refined Tar E optional with asphalt cements A, B, C, D, and refined tar F.

1. Refined tar E shall be homogeneous, free from water, and shall not foam when heated to 121° C (250° F).

2. Its specific gravity at a temperature of 25° C (77° F) shall be not less than 1.150 nor more than 1.200.

3. When tested by means of the New York Testing Laboratory Float Apparatus, the float shall not sink in water maintained at 50° C (122° F) in less than 120 nor more than 150 sec.

4. Its bitumen as determined by its solubility in chemically pure carbon disulphide at room temperature, shall be not less than 95%, and it shall show not more than 0.2% ash upon ignition of the material insoluble in carbon disulphide.

5. When distilled according to the tentative method recommended by Com. D-4, Am. Soc. Test. Mat. in 1911, it shall yield not more than 0.5% distillate at a temperature lower than 170° C (338° F); not more than 12% shall distill below 270° C (518° F) and not more than 25% shall distill below 300° C (572° F).

6. The total distillate from the test made in accordance with Clause 5 shall have a specific gravity at a temperature of 25° C (77° F) of not less than 0.980 nor more than 1.020.

7. The melting point, as determined in water by the cube method, of the pitch residue remaining after distillation to 300° C (572° F) in accordance with the test described in Clause 5, shall be not more than 75° C (167° F).

"**Refined Tar F optional with asphalt cements A, B, C, D, and refined tar E.**

1. Refined tar F shall be homogeneous, free from water, and shall not foam when heated to 121° C (250° F).

2. Its specific gravity at a temperature of 25° C (77° F) shall be not less than 1.180 nor more than 1.300.

3. When tested by means of the New York Testing Laboratory Float Apparatus, the float shall not sink in water maintained at 50° C (122° F) in less than 150 nor more than 180 sec.

4. Its bitumen as determined by its solubility in chemically pure carbon disulphide at room temperature, shall be not less than 80% nor more than 95%, and it shall show not more than 0.2% ash upon ignition of the material insoluble in carbon disulphide.

5. When distilled according to the tentative method recommended by Com. D-4 of the Am. Soc. Test. Mat. in 1911, it shall yield not more than 0.5% distillate at a temperature lower than 170° C (338° F); not more than 10% shall distill below 270° C (518° F), and not more than 20% shall distill below 300° C (572° F).

6. The total distillate from the test made in accordance with Clause 5 shall have a specific gravity at a temperature of 25° C (77° F) of not less than 1.020.

7. The melting point, as determined in water by the cube method, of the pitch residue remaining after distillation to 300° C (572° F) in accordance with the test described in Clause 5, shall be not more than 75° C (167° F).

NOTES: Asphalt cements can be manufactured from Gilsonite and asphaltic oil to meet specification A; from Texas and California asphaltic oils to meet specification B; from Mexican asphaltic oils to meet specification C; from asphaltic material from Bermudez to meet specification D. Refined tars can be manufactured from water-gas tar to meet specification E; and from coal tar or a combination of coal tar and water-gas tar to meet specification F.

"**Delivery.** The asphalt cement or refined tar shall be delivered in suitable containers, far enough in advance of its use in the work to permit the necessary tests to be made. Each container shall be plainly labelled with the trade name of the asphalt cement or refined tar, name of manufacturer, gross weight and net weight. Each shipment and each carload shall be kept separate.

"**Bills of Lading.** The contractor shall furnish the Engineer on or before the arrival of each shipment at or near the site of the work, bills of lading, or correct copies thereof, which shall state the trade name of the asphalt cement or refined tar, and the name and address of the company manufacturing and supplying it.

"**Samples** will be taken by the Engineer from each carload of asphalt cement or refined tar when delivered at the work, unless satisfactory arrangements can be made for sampling before shipment. Such samples shall be analyzed by the Engineer to assure the delivery of an asphalt cement or refined tar of the specified quality and to determine, for purpose of payment, the quantity of bitumen.

"**Work Included.** Under this item the contractor shall furnish and deliver on the work at such points as directed an asphalt cement or refined tar which conforms with the specifications of any one of the asphalt cements or refined tars given above.

"**Measurement and Payment.** The quantity of bitumen in the asphalt cement or refined tar, to be paid for under this item, shall be the number of tons, determined in accordance with the paragraph headed SAMPLES, contained in the asphalt cement or refined tar placed in the pavement in accordance with the specifications and requirements, or used as directed for other purposes. The percentage of bitumen determined by an average of the analyses of the acceptable samples taken by the Engineer during a given month shall be used as the basis for payment for the asphalt cement or refined tar used during that month. Asphalt cement or refined tar that is wasted shall not be included in the measurement under this item. The price stipulated in this item shall include the cost of furnishing, hauling and delivering the asphalt cement or refined tar at the work, and all expenses incidental thereto."

Ohio State Highway Dept. Specifications for Asphalt Cement (46) are as follows:

"**1. It shall be homogeneous in character.**

2. It shall have a specific gravity at 25° C (77° F) of not less than 0.980.

3. Its solubility at air temperature is chemically pure carbon disulphide for the following materials, or materials similar thereto, shall be at least 99.5% for pure bitumen products, 95% for Bermudez products, 81% for Cuban products and 66% for Trinidad products.

4. It shall contain not less than 15% nor more than 28%, of bitumen insoluble in 86° B paraffin naphtha.

5. The penetration for pure bitumen products shall be between 9 and 12 mm and for fluxed native asphalts between 12 and 16 mm when tested for 5 sec at 25° C (77° F) with a No. 2 needle weighed with 100 g.

6. When 20 g of the material are heated for 5 hr in a cylindrical tin dish approximately 2½ in in diameter by ¾ in high at a temperature of 163° C (325° F) the loss in weight shall not exceed 5%. The penetration, 5 sec, 25° C (77° F), No. 2 needle, 100 g weight, of this residue shall be at least 50% of the original penetration.

7. Its fixed carbon shall be not less than 8% nor more than 16%.

8. It shall have a ductility at 25° C (77° F) of not less than 30 cm, Dow mold.

9. Of the total bitumen not more than 1% by weight shall be insoluble in chemically pure carbon tetrachloride.

10. The flash point in open cup shall be not less than 180° C (356° F).

11. It shall be free from water and shall not foam when heated to 177° C (350° F).

12. All bituminous material used in a given construction shall be uniform in character, appearance and viscosity."

Oakland, Cal., Specifications for Asphaltic Oil. For method of use, see Art. 11, Method G.

"The Oil used shall be a natural oil of an asphaltic base, treated to remove water or sediment, or the residuum of such an oil from which the volatile material has been removed by distillation. It must not have been injured by overheating, and it must not be a mixture of solid asphalt and lighter oils or distillates.

"Asphalt. The oil shall contain not less than 88% of asphalt having, at a temperature of 25° C (77° F), a penetration of 80 District of Columbia Standard. The amount of asphalt in the oil shall be determined by heating 25 g of said oil or residuum in a cylindrical metal dish in an oven, first at a temperature of 121° C (250° F) to a constant weight, and then at a temperature of 204° C (400° F) until it has reached the proper consistency when the residue shall be weighed. The metal dish specified in this test shall be between 2¼ and 2½ in in diameter, and between ¾ and 1 in in depth.

"Consistency and Volatility. When brought upon the street, the oil shall have a penetration of not less than 200 District of Columbia Standard. The oil shall lose not more than 1½% of volatile matter when heated, as above described, at a temperature of 121° C (250° F) to a constant weight. The residue in the dish, after being heated, as above described, at a temperature of 121° C (250° F) to a constant weight, shall be further heated at a temperature of 163° C (325° F) for 5 hr. The penetration of the residue after such heating shall not be less than 100 nor more than 400 District of Columbia Standard.

"Fixed Carbon. The oil shall yield not less than 3% nor more than 12% of fixed carbon.

"Organic Impurities. The oil shall contain not more than 0.2% of bituminous matter insoluble in carbon tetrachloride at temperatures between 15° and 21° C (60° and 70° F). It shall contain no free carbon and shall be free from the odor of tar.

"Adhesiveness. The oil shall show an adhesive strength of not less than 160 sec per rev when tested at a temperature of 25° C (77° F) on the Osborne Adhesive Test Apparatus in the laboratory maintained by the Street Department of the City of Oakland."

British Standard Specification for Pitch, based on specifications of the Road Board of England and adopted in 1916 by the Engineering Standards Com. of Great Britain (12).

"1. General. This pitch is suitable for pitch-grouting. See Road Board of England General Directions for Pitch-Grouting, Art. 11.

"2. Consistency. The pitch is obtained of the required consistency most conveniently by running it off from tar stills in which the distillation of the tar has been stopped at the point at which the residual pitch will give a penetration of 70, or such

other penetration as may be specified to suit climatic or local conditions, when tested at 25° C (77° F) on a penetrometer. Harder pitch may be softened or cut back, in the still or in a mixer at the tar works, to the extent necessary for it to give this penetration, by the addition of tar oil of the grade specified below in Clauses 7 to 10. Where pitch of the required consistency is not thus directly procurable, it may be prepared by softening commercial soft pitch, as specified below in Clauses 4 to 6, by the addition of tar oil as specified below in Clauses 7 to 10. In preparing the softened pitch in this manner the tar oil is added to the pitch in the manner described under Instructions for Melting the Pitch in the Road Board General Directions for Surfacing with Pitch-Grouted Macadam, in such proportions that the resultant softened pitch will give a penetration of 70, or such other penetration as may be specified to suit climatic or local conditions, when tested at 25° C (77° F) on a penetrometer, with a No. 2 needle weighed to 100 g for 5 sec.

"3. Prepared Pitch from Tar Distilleries. General Characteristics. Pitch which has been procured of the required consistency directly from a tar distillery needs only to be thoroly melted in the pitch heaters or boilers, but as a precaution against burning, 1 to 2% of tar oil may advantageously be put into the boilers with the pitch. Pitch which has been procured of the required consistency directly from a tar distillery shall not yield more than 4% of distillate below 270° C (518° F) on distillation as described in Clause 5, and shall contain not less than 16% and not more than 28% of free carbon, as defined below in Clause 6.

"4. Commercial Soft Pitch. The pitch shall be derived wholly from tar produced in the carbonization of coal, except that it may contain not more than 25% of pitch derived from tar produced in the manufacture of carburetted water-gas.

"5. Fractionation. On distillation in a litre fractionating flask, a distillation flask without special fractionating column, ½ to ⅔ filled, the pitch shall yield the proportions by weight of distillates stated below; the temperatures of distillation being read on a thermometer of which the bulb is opposite the side tube of the flask: Below 270° C (518° F), not more than 1% of distillate; between 270° and 315° C (518° and 599° F) not less than 2% and not more than 5% of distillate.

"6. Free Carbon. The pitch shall contain not less than 18% and not more than 31% by weight of free carbon. The free carbon is to be determined by the weight of the residue after complete extraction of all matter soluble in benzol or disulphide of carbon. The extraction is best carried out in a Soxhlet or similar apparatus by disulphide of carbon followed by benzol.

"7. Tar Oil. Source of Tar Oil. The tar oil to be used is preferably a filtered green or anthracene oil, and shall be derived wholly from tar produced in the carbonization of coal or from such tar mixed with not more than 25% of its volume of tar produced in the manufacture of carburetted water-gas.

"8. Specific Gravity. The specific gravity of the tar oil at 20° C (68° F) shall lie between 1.065 and 1.085.

"9. Freedom from Naphthalene and Anthracene. The tar oil after standing for ½ hr at 20° C (68° F) shall remain clear and free from solid matter, naphthalene, anthracene, etc.

"10. Fractionation. The tar oil shall be commercially free from light oils and water. On distillation in a litre fractionating flask, a distillation flask without special fractionating column, ½ to ⅔ filled, the tar oil shall yield the proportions by weight of distillates stated below; the temperatures of distillation being read on a thermometer of which the bulb is opposite the side tube of the flask: Below 170° C (338° F), not more than 1% of distillate, light oils and water, if any; below 270° C (518° F), not more than 30% of distillate, middle oils, and light oils and water, if any; below 330° C (626° F), not less than 95% of distillate, heavy oils, middle oils, and light oils and water, if any."

CONSTRUCTION

9. Mechanical Appliances

In the various methods of constructing the wearing course, the bituminous material is distributed by hand-pouring applications, gravity distributors and pressure distributors. For descriptions and factors governing

selection of vehicular distributors, see Sect. 14, Art. 6. It is evident that uniform application of the bituminous material will depend upon the suitability and the careful manipulation of the method of distribution employed. In using vehicular distributors, one cause of uneven distribution of the bituminous material is overlapping of applications. The use of strips of tar or wrapping paper, from 3 to 5 ft in width, placed at the edge of an application has prevented sections of the wearing course receiving double the amount of bituminous cement specified.

Pouring cans have been used extensively, and in some cases remarkably successful results have been secured. Their satisfactory use requires expert and painstaking supervision. Where the construction work is done by well-trained labor of a highway department and under the direction of an experienced engineer, it is possible to efficiently use this method of distribution; as examples, the Pitchmac pavements of Liverpool (see Art. 10) and bituminous macadam pavements of Alexandria, Va. (see Arts. 9 and 12) may be cited. Due to the extreme variability in the experience and quality of work of labor and contractors, the hand-pouring method should not be used on work covered by the usual type of contract (without qualification requirements) used in the United States. The same comments apply to the use of hand-drawn pressure distributors and all types of gravity distributors.

Pressure distributors vary in many details of construction and operation. It is essential, therefore, in connection with contract work to include in specifications definite requirements covering the variable factors. Unessential details should not be included as competition on contract work will thereby be curtailed. The specification should, however, include requirements which will insure the use of machines suitable for the method and the types and grades of bituminous materials employed, the prevention of formation of ruts and the disturbance of the wearing course, and ease in manipulation and supervision. As an example of a good general specification, that of the Am. Soc. Mun. Imp. is cited. Most types of pressure distributors which are drawn by road rollers or tractors or are mounted on motor truck chassis, have been employed in the construction of bituminous macadam pavements as well as for the construction and maintenance of bituminous surfaces (see Sect. 14, Art. 6). Some machines, however, have been especially designed for penetration work; as for example, a distributor having its bituminous material tank and distributing apparatus mounted on a sectional roller, the pressure being furnished by an air compressor attached to a steam road roller or tractor.

Am. Soc. Mun. Imp. Specification for Pressure Distributor. To secure uniform distribution and to provide for such details as means of control of proper pressure and temperature and prevention of rutting of the wearing course during construction, the Am. Soc. Mun. Imp. prescribed in its 1917 specifications the following requirements: "The pressure distributor employed shall be so designed and operated as to distribute the bituminous materials specified uniformly under a pressure of not less than 20 lb nor more than 75 lb per sq in in the amount and between the limits of temperature specified. It shall be supplied with an accurate stationary thermometer in the tank containing the bituminous material and with an accurate pressure gauge so located, as to be easily observed by the Engineer while walking beside the distributor. It shall be so operated that, at the termination of each run, the bituminous material will be at once shut off. It shall be so designed that the normal width of application shall be not less than 6 ft and so that it will be possible on either side of the machine to apply widths of not more than 2 ft. The distributor shall be provided with wheels having tires each of which shall not be less than 18 in in width, the allowed maximum pressure per sq in of tire being dependent upon the following relationship between the aforesaid pressure and the diameter of the wheel: For a 2-ft diameter wheel, 250 lb

shall be the maximum pressure per lin in of width of tire per wheel, an additional pressure of 20 lb per in being allowed for each additional 3 in in diameter."

Efficient Method of Using Pouring Cans in Alexandria, Va., as described by E. C. Dunn, City Engineer (28). For details of cost of construction in 1916, see Art. 12. "The standard work is built 8 in thick, the base being 5 in of locomotive cinder concrete, and the top 3 in of broken stone and asphalt. The stone herein called 1½-in stone is the crusher product between 1¼ and 2¼-in; ¾-in stone is the crusher product between ⅝ and 1¼-in; and stone chips is the crusher product between ¼ and ⅝-in.

"For the concrete a rather poor mixture is used, about 1:3½:8. As fast as the concrete is laid, it is uniformly covered with about 50 lb per sq yd of 1½-in stone, and rammed to a generally uniform surface, but not a smooth one, the object being to imbed the stone, and yet leave a rough finish. The general plane of the rammed concrete is 3 in below the finished grade with the stone projecting.

"The first course of 1½-in stone is hauled over the concrete, dumped on sheet iron plates, and shoveled into place and raked to the approximate finished grade and surface. The amount of stone in this course averages 220 lb per sq yd. Thoro rolling, a d the elimination of surface inequalities is considered necessary before the asphalt is poured.

"The first coat of asphalt, from 60 to 67% of the total amount used, is poured into the first coat of stone, diagonally across the road from 8-in spout pots, in measured lengths calculated to uniformly take the contents of a pot as averagely filled at the heating kettle. In pouring wider spaces than the ordinary the tape line is held for each pot, but always each pouring is in the opposite direction from the adjoining one. Two men do the pouring, one starting at one side of the road and the other starting at the other, and a third man, using a pot with spout opening about $^3/_{16}$ by 1 in, fills in any place not covered by the other two. Constant check is kept on the distance. Effort is made to keep the asphalt at the temperature at which it flows freely without objectionable spattering. With the asphalt in this condition the men pour a more uniform width without lapping or leaving streaks; keep a more uniform rate of speed across the road, and a thicker coating is held on the stone in the upper portion of the course than when the asphalt is at a higher temperature; and the penetration is sufficient. The pourers quickly learn the knack of walking faster when starting with the pot full and slowing up when it is emptied so that the rate of distribution is practically uniform.

"Progressively with the pouring an average of 50 lb per sq yd of ¾-in stone is spread as uniformly as possible on the asphalt immediately after it is poured. Men with street brooms follow the stone spreaders, smoothing out the stone when lumped, and covering any omitted space and the roller keeps up as close as possible in order to roll in the stone while the asphalt is hot. The rolling is continued until the stone crushes, when the entire surface is lightly broomed and then it is rolled again. The operation is repeated one or more times until the resulting surface presents a uniformity of smaller stone than that originally spread, the surface voids in the underlying course of stone apparently filled and the asphalt surface apparently covered. Some judgment should be exercised according to the material used; excessive crushing tending to produce an impervious surface over the underlying work. Usually no brooming is done after the last rolling of this coat.

"The second coat of asphalt, from 40 to 33% of the total amount used, is poured into the second course of stone in the same manner described for the first coat, except that the distance diagonal measured is laid out across the road for one half a pot and in a direction to cross the pouring lines of the first coat, and the pourers cross the road and return in pouring the full pot, and both pourers start from the same side.

"The finished coat of chips, averaging 30 lb per sq yd, is spread, rolled, broomed and rerolled as described for the second course of stone. The completed road is finished ½ in higher than grade and the ultimately compressed surface.

"The general results (of the 1915 and 1916 work) have been good to the present time (1917). No ravels, ruts or waves have developed and no bleeding sufficient to require sanding, and nothing has been spent for repairs on any section in which asphalt was used. The surface texture has become smoother each year and only a minimum of large stone show on the oldest sections. However, in comparison with the higher class pavements, the roads fall short of perfect conformity to grade and section. The slight inequalities seem hard to overcome with any justifiable expense, and are prob-

ably due to one or a combination of the following: The separation of the larger from the smaller stone in the first course; the unyielding concrete base with the small available roller used; and insufficient care at times in placing and spreading the stone. An objectional feature is that usually the work does not smooth out until the summer after the work is laid. In the interim there are the apparent necessity, and the temptation to apply a surface treatment, but as yet this has not been done on any asphalt work.

"It has been found that care for the following points tend to better uniformity in the work, and while self-evidently necessary are apt to have insufficient attention, especially in rush work: A uniformly surfaced concrete, the spreading of the first course of stone with shovels and the elimination of inequalities in this course, the lapping or the not joining of the main pouring widths, the constant check on the distance poured, the neglect of the pourers to evenly fill the entirely empty pots and the injudicious or excessive use of the spouted pot in filling in omissions. The men spreading the ¾-in stone and chips should be particularly expert. Ordinary broadcasting is not allowed. To these may be added the prompt spreading and rolling of stone on the asphalt coats and the manipulation and expert inspection of the second stone course."

10. Methods of Construction

General Considerations. In the construction of bituminous macadam pavements it is desired to secure, (1) a stable wearing course consisting of broken stone or similar material thoroly rolled so that it will be well compacted and keyed together and with the several sizes of material uniformly distributed, and (2) a uniform distribution and penetration of the bituminous material within the upper 1½ to 3 in of the crust. Several methods of construction have been devised with a view to meeting the above prerequisites. Careful supervision, based on experience, is necessary to prevent non-uniformity in the density of the wearing course of broken stone and in the amount of bituminous material applied per square yard.

Some bituminous macadam pavements are designed with the intent of constructing a pavement which, in durability, will lie between a water-bound broken stone road with a bituminous surface and a bituminous concrete. In this class, a penetration of the bituminous cement into a thoroly rolled wearing course to a maximum depth of 1½-in is desired. This type, when finished with a seal coat, has proved especially efficient. In other types, the object is to secure a bituminous coating on all particles of road metal comprising the wearing course or for at least a depth of 2 to 2½-in. There are many examples of excellent pavements constructed by this method. Pitchmac, as built in Liverpool, is one of the best types designed with the idea of constructing, by penetration methods, a bituminous wearing course which will have the characteristics of a properly constructed bituminous concrete having a mineral aggregate of broken stone, that is, all particles uniformly coated and thoroly keyed together. Due to the fact that light rolling of the broken stone prior to the application of the bituminous cement is often specified in these types, many failures have occurred due to lack of stability of the wearing course.

The pavement is generally built in 2 or 3 courses, the foundation course or courses being from 4 to 8 in thick after rolling, and the top course from 2 to 3 in after rolling. A foundation of broken stone is usually composed of the product of a crusher which passes over a screen with 1½-in circular holes and thru a screen with 2½-in circular holes, or over a 2½-in and thru a 3½-in screen, or over and thru screens having openings of similar dimensions. The foundation should be thoroly compacted with a 10 to 15-ton roller prior to the construction of the wearing course. The manner of finishing this course varies in the several methods, as will be noted later.

The crown of bituminous macadam pavements should not exceed ½ in per ft.

Conclusions. Spec. Com. Mat. Road. Cons., Am. Soc. C. E. (16f). "The crown should not exceed ½ in per ft and should never be less than ¼ in per ft.

"The principles relating to thickness applicable to a broken stone road are likewise applicable to bituminous macadam pavements, and thoro rolling, including the rolling of the upper course, both before and after the application of the bituminous material, is also necessary. As it is desired to bind only the upper course with bituminous material, it is necessary, in order to prevent waste by penetration, that there should be no appreciable voids in the next lower course. It is not necessary, however, to flush the filler or binder in this course to the same extent as is necessary in binding the top course of a water-bound road, and it is absolutely essential that no binder should cover the stones of the lower course when the top course is spread.

"The quantity of bituminous material used should be only sufficient to penetrate thru the upper course. The quantity per square yard cannot be prescribed absolutely, depending in some degree on the hardness and size of stone used, but, in general the application of 1 gal or less to the square yard for each inch in thickness of the finished upper course is adequate.

"The use of a distributor in applying the bituminous material is essential, and the distributor should be of such type that absolutely uniform application may be accomplished, and that no ruts are formed in the surface by the wheels supporting the distributor. The bituminous material should be applied at such a temperature that it will flow freely, and, to insure proper penetration, the stone should be dry and clean, and the air temperature s ould not be lower than 10° C (50° F) during application.

"In order to secure a proper surface, the covering material should preferably consist of the crusher product passing over a ¼-in screen and thru a ¾-in screen. Finer material, however, may be used for covering if a slippery surface is not objectionable but the use of material passing thru a 10-mesh sieve should be avoided.

"The use of a bituminous material by no means justifies any lack of care in the ordinary details to be followed, but rather increases the need for thoroness and skilled supervision. The main principles underlying good construction in water-bound roads remain in full force when such roads are treated with bituminous material."

Conclusions on Amount and Method of Distribution of Bituminous Material by Ill. Highway Comm. (40a). "It is necessary that the bituminous binder be spread so as to present as uniform a surface as possible. This may not necessarily mean the uniform distribution of the binder as the texture of the surface of the macadam before the application of the binder may itself not be quite uniform. Therefore, the more finely divided form in which the asphalt can be applied, the better the control of its distribution. The form of the application whereby the material is spread by a jet of steam has given excellent results. Too much binder should not be used as it will result in a less stable layer of bituminous macadam than if sufficient binder is used only to fill the voids in the stone. It is essential that the surface of the road have very close texture and that usually this can not be secured in less than three applications except by an excessive amount of binder. The most economical and best results can be secured when the binder is put on in three applications."

Conclusions on Rolling, by Hubbard (38a). "It should be thoroly compacted by rolling until the fragments of broken stone have just keyed together. It is generally believed that an excess of rolling should be avoided in order not to close up the surface to such an extent that satisfactory penetration of the bituminous material will be prevented. While this is true, the general tendency is to go to the other extreme and the almost fatal mistake is made of not rolling enough. It is a fact but little appreciated that almost all of the compaction of the large stone in the wearing course is obtained prior to application of the bituminous material. It is therefore exceedingly poor practice to merely smooth out the top course of stone before applying the bituminous material, as is required by some specifications. The rapid deterioration and unsatisfactory condition of many bituminous macadam pavements are in large measure due to lack of rolling during the initial stages of construction, which makes it difficult, if not impossible, to properly consolidate the road after application of the bituminous material. A rapid cooling of the bituminous material takes place after application, which results in a false set of the course of top stone, if it has not

previously been keyed together by rolling. In even moderately cool weather and especially after application of a layer of finer stone, this false set is difficult to completely break down by ordinary rolling. Moreover, if broken, a true set will be seldom obtained because of the thickness of the coating of bituminous material on the stone fragments which, under pressure of the roller, tend to slide about rather than to key together. The principles here involved are commonly recognized in the construction of the ordinary types of bituminous concrete pavements where compression is only attempted on well-mixed and usually preheated bituminous aggregates carrying carefully controlled percentages of bituminous material. Lack of initial rolling in a bituminous macadam is almost invariably followed by waviness and ruts produced by traffic. It may usually be detected by the comparative ease with which the top course may be pried up with a screw driver or other hand tool."

Sharples (47) states that "The greatest of care must be used in rolling this course. The surface must be well knit together, smooth and firm. At the same time it must be open enough to admit the bituminous material. The engineer must watch the stone carefully to see that it is not crushed too much, as in this case the door will be closed to the entrance of the bituminous material and it will be left as a mat on the surface instead of entering between the stones to bind them together. On the other hand the stone must not be too open, as in that case the binder will run thru to the bottom of the course. If the stone is very hard, it may be advisable to add a small quantity of ¾-in stone just previous to the last rolling, to reduce the void space. After the rolling is finished, the stone should be 2½ in in depth."

Conclusions on Crown by Meeker (16a). "In building some of the first bituminous roads in New Jersey, it was found that if a crown of ¾ or 1 in per ft was used, the surface would be slippery. The speaker believes that no road with a bituminous surface should have a crown of more than ½ in per ft, or, if the road is wide, ⅜ in per ft is ample. If a proper crown is used, the objection of slipperiness can be prevented by immediately covering any bituminous application with a layer of stone screenings or sharp sand, and in this way a fairly gritty surface may be obtained."

Method A. In this method, the road metal of the wearing course, which is laid on a foundation course as described above, consists of one product of broken stone, ranging in size from a product whose particles vary from 1½ to ½-in in longest dimensions to a product passing over a 1½-in and thru a 2½-in screen, or similar thereto. A typical mechanical analysis of a product, the use of which has given satisfactory results, follows:

Passing ¼-in screen, trace
Passing ½-in screen, 18.9%
Passing ¾-in screen, 43.1%
Passing 1-in screen, 34.4%
Passing 1¼-in screen, 3.6%

After the wearing course is laid the bituminous material is applied, either before or after the broken stone is rolled, some engineers preferring the former method because of the greater depth of penetration secured. To secure the best results, the wearing course should be thoroly rolled prior to the application of the bituminous material in order to secure a well compacted and stable course of broken stone, mechanically interlocked and bound together. If the rolling is postponed until after the application of the bituminous material, the wheels of the roller may have to be wet or oiled to avoid picking up the surface. After the application of the bituminous material, a coat of mineral matter should be spread over the surface of the course and rolled. The total amount of bituminous material used in this method varies from ½ to 2½ gal per sq yd. For specifications, see Art. 11, Method A.

Method B. In case the metalling of the wearing course is a uniform product of about 1 or 1½-in in size or a product similar to or larger than one passing over a 1½-in and thru a 2½-in screen, usually the voids in the upper part of the wearing course are filled after the bituminous cement is

applied. Practice varies with reference to the amount of rolling of the wearing course prior to the application of the bituminous cement. For traffic, medium or heavy in weight and amount, the best results have been secured by thoroly rolling the road metal and thus securing maximum interlocking of the particles and thereby obtaining the highest degree of stability practicable by this method. The bituminous cement is applied in an amount varying from 1½ to 2 gal per sq yd, after which ⅜-in stone chips or a product similar to one passing a ½-in and thru a 1-in screen is spread and thoroly rolled. Usually the surface is then broomed with stiff brooms, removing the excess loose broken stone, and another coat of bituminous cement, from ½ to 1 gal per sq yd, is applied, covered with a layer of stone chips or pea gravel and rolled. For specifications, see Art. 11, METHOD B.

Strong (51), when constructing a wearing course of broken stone which is less than 2½-in and greater than 1½-in and employing broken stone less than 1½-in and greater than ⅝-in for the filler after the first application of the bituminous cement is deposited, uses the following rules for the total amount of bituminous cement to be used, dependent upon the physical properties of the broken stone employed. In cases where the stone is of low crushing and abrasive strength, a total of 0.9 gal is used for each inch in depth of the compacted wearing course. In cases where the stone is of better material such as trap, 0.82 gal is used for each inch in depth of compacted wearing course. The total amount of bituminous cement is applied in two applications, the first to be ⅔ of the total amount and the second, applied after the filler is spread, rolled and the surplus removed, ⅓ of the total amount. It is insisted that the applications of bituminous cement should be made with pressure distributors. If hand pouring is used it is dangerous to attempt to use the above quantities as uneven distribution of the binder, which is unavoidable, invariably leads to the development of fat spots.

Method C. This method is often used when the road metal composing the wearing course varies from 2 to 3½-in or from 2½ to 4-in. After lightly rolling the wearing course, coarse sand, stone chips or pea gravel is spread and broomed until the voids of the metalling are partially filled. Usually the road metal is again lightly rolled and any surplus material is broomed off the surface. The bituminous cement is then applied, using from 1¼ to 2 gal per sq yd. This coat is covered with a layer of pea gravel, screened stone chips or larger broken stone and thoroly rolled. Sometimes a seal coat of from ½ to 1 gal of bituminous cement is used with this method. For specifications, see Art. 11, METHOD C.

Ohio State Highway Dept. Method Using Soft Stone (30b). "The usual specifications for bituminous macadam pavements limit the size of the stones composing the surfacing material to a maximum that will pass a 2½-in ring. These specifications have given satisfaction with trap rock and granite, but with softer varieties of rock such as limestone there is a tendency for the stone to powder and crush under the roller and to wear under traffic, which makes a larger sized aggregate desirable. To meet these conditions the Ohio State Highway Dept. has been experimenting with the use of a surfacing stone that will pass a 4-in ring and be retained on a 2½-in ring. The voids in this material are partly filled with sand, stone dust and chips, altho thoro rolling ordinarily breaks up enough of the material to make a fairly compact layer.

"The method of construction is to spread and harrow the stone as for a water-bound macadam road. As soon as the stone is partly compacted, stone chips and stone dust are spread into the voids with shovels. Rolling and the application of screenings are continued until the layer of stone is thoroly compacted and the voids sufficiently filled so that the amount of bituminous material to be used will produce a dense mixture. The bituminous binder is applied by the penetration method with any approved form of apparatus. After the application of the bituminous binder the surface of the pavement is spread with screened washed gravel ¼ to 1 in in size. After rolling

the gravel in, a seal coat of the same bituminous material is applied and more gravel is added, followed by more rolling. A total application of about 2 gal per sq yd for a 3-in depth of rolled stone gives excellent results. Washed gravel instead of limestone chips is used, as the available gravel is usually harder and tougher than ordinary limestone and the cost is about the same. A finer gravel, ¼ to ⅝-in, is preferable for the seal coat. For a 4-in road the amount of bituminous binder required is about 2¼ gal per sq yd. It is reported that these pavements have given much better satisfaction than the older ones that were constructed with the 2½-in stone as aggregate."

Method D. A bituminous macadam pavement called Pitchmac by its inventor J. A. Brodie, City Engineer of Liverpool, has been used to a considerable extent in England and has been adopted as a standard type by the Road Board of England. It is constructed on a foundation of stone. The wearing course of broken stone varies from 2 to 4½ in in depth, dependent upon traffic conditions. If the wearing course is from 2 to 3 in in thickness, it is constructed in 1 layer, and if from 4 to 4½ in, in 2 layers. The single layer and, in the case of 2 layers, the upper layer is composed of broken stone ranging in size from 1¼ to 2½ in. After thoro rolling the bituminous material is applied to the single layer or to each of the layers of the 2-layer wearing course. The bituminous compound used in England consists of hot sand mixed with tar pitch. From 1¼ to 2 gal per sq yd are used for the 1-layer wearing course and from 3¼ to 3½ gal for two layers. To assist in completely filling the voids, chips varying in size from ⅜ to ¾ in are applied during the rolling of the bituminous grouted layer. This type of pavement has been used to a limited extent in Massachusetts, see (24). For specifications for the bituminous mastic used in England, see Art. 7, and for the construction specifications of the Road Board of England and Massachusetts, see Art. 11.

Liverpool Practice. Brodie states (5) that "pitch grouted macadam has been found to give most satisfactory results in streets of medium and light traffic, and is now being largely used in place of ordinary macadam, and also of more expensive pavements. It is laid to a depth of from 3½ to 4½ in, in two layers. Welsh granite macadam is used, broken to a 2½-in gauge for the lower layer and to 1½-in for the top surface. Each layer is put down dry and continually rolled before and after the grouting of pitch and sand mixture has been applied, until the surface is thoroly consolidated. The foundation is generally of hand-pitched rock, 10 in deep as for ordinary macadam, but in some cases a bed of 6-in concrete has been used on main roads. Pitch macadam is also being much used as a surface covering for old boulder pavements, many of which still exist in Liverpool in old streets where the traffic is very small. The cost of pitch macadam may be taken at 1s (24 cents) per sq yd per in of depth.

"The oldest sample of pitch macadam in Liverpool was laid in Princess Ave. in 1901, near the end of Eversley St., and has been in continuous use ever since without repair. Other lengths of pitch macadam in this avenue were laid at various dates between 1906 and 1908. This avenue carries a large volume of light motor and carriage traffic, as well as some of a heavier character, the traffic amounting to 120 000 tons per yd width per annum."

Method E. When the metalling of the wearing course is of a large and uniform size, another method employed is to place a layer of sand ¾ in thick on the bottom course, the voids of which have been filled. The bituminous cement is then distributed on this layer, using about 1 gal per sq yd. The upper course of metalling is immediately placed on the mastic and rolled. Continued rolling forces the material of the upper course down and draws the bituminous mastic up into the voids. A coat of bituminous cement, using about 1¾ gal per sq yd, is then applied to the surface of the upper course. A layer of ⅜-in stone, ½ to ¾ in thick, is spread over this and rolled. The work may stop here or may be carried on a step further

by brooming off the excess $\frac{3}{8}$-in stone, afterwards applying another coat of bituminous cement, $\frac{1}{2}$-gal per sq yd, adding a layer of screened stone chips and rolling the same. The Gladwell system, as used to a limited extent in England, is essentially the same in principle except that a course of screened stone chips mixed with bituminous material is substituted for the sand layer and its coat of bituminous material. For specifications, see Art. 11, METHOD E.

Method E Used with a Cement-Concrete Foundation as described by Brigham (22). "The top-course specifications called for cleaning the concrete, after which high-carbon binder tar was applied at the rate of $\frac{1}{2}$ gal per sq yd. The tar was heated to about 121° C (250° F) in the tank cars in which it was shipped, and applied at from 40 to 50 lb pressure. The pressure distributor was hauled by a tractor, which also furnished steam to run the air-pressure pump. Immediately after applying the tar, $\frac{3}{4}$-in stone was spread, only enough being used to keep the tar from picking up while being rolled. A 10-ton roller was then started, and the rolling and spreading continued together until about 1-in, loose measure, of $\frac{3}{4}$-in stone was applied. Enough of this size stone was used so that no tar came to the surface, yet each stone was bedded in tar. A second application of tar, $\frac{1}{2}$ gal per sq yd, was distributed as described, and this was covered at once with a thin layer of screenings. As before, the rolling and spreading of the stone were carried on simultaneously. It required about $\frac{3}{4}$ in, loose measure, of screenings to prevent the pavement from bleeding. In building this top course it was found that the first layer of stone could be rolled too much, forming a thin layer of dust to which it was hard to make the second coating of tar bind, but thoro rolling of the second application improved the pavement. With an average of 5 men sweeping and 15 men spreading stone, the progress was about 1500 lin ft of finished wearing course a day.

"The cost per square yard of the pavement was as follows: 1 : $2\frac{1}{2}$: 5 concrete foundation, 5 in thick, \$0.708; top course, including stone and tar, in place, complete, \$0.2225; total cost of pavement, \$0.9305.

"For comparison there are listed below the average costs per square yard of several of the common types of pavement built in this section of New York State and compiled from data in the 1915 Bulletin of the Highway Comm.: Water-bound macadam, 15 roads, \$0.737; water-bound macadam with hot or cold oil surfacing, 13 roads, \$0.8103; grouted bituminous macadam, 23 roads, \$0.946; concrete pavement, 27 roads, \$1.117; 1 : $2\frac{1}{2}$: 5 concrete foundation with open mix bituminous concrete top course, 7 roads, \$1.335.

"It is readily seen from the foregoing data that in first cost the tar-macadam top course on a concrete foundation is nearly the same as the grouted bituminous macadam and considerably less than concrete pavement. In regard to these three competing types of medium-priced pavements, the composite type has many distinct advantages. Practically all failures of macadam roads can be traced to poor foundation. The stone of the lower courses sinks into any soft spots in the subgrade and the top course follows. This forms a pot-hole which is a source of constant trouble and maintenance expense and makes a rough road for the traveling public. In a pavement with a concrete foundation, the concrete bridges over these weak points in the subgrade, thus eliminating one of the worst features of an all stone pavement. Concrete pavement, while a type requiring little maintenance, is high in first cost, needs care in construction and in the choice of the materials used as ingredients, and is slippery and hard for horse traffic. No expansion joints are needed in the composite type of pavement, as the bituminous macadam mat keeps moisture and temperature conditions constant in the slab, thus protecting it from extreme changes resulting in cracking and displacement. Should the base crack, as it is not exposed to traffic, it requires no maintenance. The only maintenance necessary for this pavement, therefore, is to patch the wearing course as weak spots develop and to clean ditches and culverts. Possibly every 3 or 4 years a light oil should be applied to enliven the old bituminous material. This leaves the composite type of pavement with the following advantages: Low first cost; low annual maintenance charge; simple to construct; less care in selecting the materials entering into its structure; permanent base on which to build any type of surfacing, should the original wear out; and smooth and resilient surface for automobilists and horsemen."

Method E. Gladwell System as described by Gladwell and Manning (7).

BITUMINOUS BINDER. "The bituminous binder or matrix used under this system is composed of clean, thoroly dried granite chippings, free from dust, and such as will pass thru a ¼-mesh sieve. The procedure to be followed in the manufacture of the binder is to dry the chippings in an ordinary hot plate or portable sand drier, and, when still warm, but at a temperature not exceeding 38° C (100° F), mix with a refined tar. The composition is heated to about 79° C (175° F) and is then thoroly incorporated with the chippings, by applying the liquid gradually, and turning the mass until the whole forms a lively, plastic, bituminous matrix or binder. A mixture consisting of 15 gal of composition per 1 cu yd of chippings is a practical average composition.

LAYING THE AGGREGATE. "Upon the foundation already prepared and cleaned, lay a cushion of the prepared matrix or sub-binder, say about 6 ft in length and to the half width of the road, using 1 cu yd of sub-binder for each 46 sq yd of surface, or thereabouts; this should be spread evenly and lightly, and on no account should it be tramped on or consolidated until the aggregate is spread as hereunder described. This stone should be clean and true to gauge, preferably 2-in to 2½-in. The average road stone broken to 2-in gauge will cover 11 to 12 sq yd per ton as a two-stone coat. Spread the same as closely and evenly as possible, giving a two-stone coat, and using ordinary stone forks, so as to leave the smaller flaky pieces of stone, as well as all dust and rubbish, behind as waste. By adopting and repeating this method the men will be enabled to lay both sub-binder and aggregate without trampling on either. Take care that a raw edge of sub-binder and aggregate is always left at the half-way width of the road, to ensure a satisfactory joint when the remaining half-way width is re-surfaced.

ROLLING THE AGGREGATE. "Rolling should be commenced as soon as a section of about 25 or 30 yd in length has been laid, the metalling gang being kept as busily employed as possible in laying a further length of materials. The best results under this system will be found to accrue from the use of a fairly light roller, the object being to gently press the aggregate down into the sub-binder, and at the same time to entice the latter in an upward direction so as to fill the voids in the aggregate. The roller should be driven over the newly-laid materials at its lowest speed, and after a few journeys over the surface it will be found that the sub-binder is working up between the voids in the aggregate; immediately apply to the newly-rolled surface by sprinkling, not entirely covering, some of the same material as has already been referred to as the sub-binder, but which now becomes the top or super-binder. Lightly brush this super-binder into the surface voids in the aggregate until the same are fairly well filled, and continue rolling until the new surface of the road is solid.

SEALING THE SURFACE. "The surface should be sealed, which is carried out by either one or other of the following methods. In warm, dry weather, a considerable superficial area of road may be surface sealed at one operation, by means of one of the mechanical tar-spreading machines. If a mechanical spreader is used, it will be advisable to use a larger percentage of the super-binder than when hand-sealing is resorted to, while the quantity of composition necessary will be somewhat reduced, 1 gal being considered sufficient for 6 or 7 sq yd. If it is considered preferable to surface-seal the road as the work proceeds, this can be readily done by hand labor. The quantity of tar used in carrying out this operation varies in proportion to the quantity of super-binder used in the consolidation, and the amount of rolling the road has received, and will be found to range from ¼ to ½ gal per sq yd. One ton of ¼-in gauge granite chippings will be found sufficient to easily cover 150 sq yd of sealed surface. After the chippings are spread, the road should be well rolled and thoroly compacted."

Method F. In order to secure uniform sizes of road metal in the course upon which is to be applied the first application of bituminous binder, in some cases recourse has been had to harrowing. After harrowing, the course is shaped and thoroly compacted before the bituminous material is applied. With the limestones commonly used in Illinois, this method has produced satisfactory results when suitable asphalt or tar cements have been properly used in accordance with the specification of the Ill. State Highway Dept. For details of construction, see Art. 11, METHOD F.

Method G. In some cases, when heavy asphaltic oil has been used for the bituminous cement, the following method has been employed. Upon a course of broken stone, prior to rolling, about ½ gal per sq yd of asphaltic oil is distributed. The course is then harrowed, after which the second application of about ½ gal per sq yd is made. The course is next thoroly rolled during which screenings are spread. In some cases the pavement is finished by a third application of ½ gal per sq yd of oil, screened and rolled. In other cases, the third treatment is followed by a fourth using from ¼ to ⅓ gal per sq yd. See Oakland, Cal., specifications, Arts. 6, 8 and 11.

Bituminous Gravel Pavements. The use of gravel in the construction of bituminous pavements by penetration methods has been usually limited to those localities where broken stone costs more than gravel. It is self-evident that it is impracticable to secure the same keying effect with gravel as can generally be obtained with broken stone.

Bituminous Gravel Pavement in Longview, Texas. The method of construction and the conclusions relative thereto, as contained in the following abstracts of a description by Green (37), are typical of the practice of many engineers who have used gravel in this class of work.

"Crushed limestone delivered on the streets cost about $3.25 per yd, and even at that price was not the best material, being soft and dusty. A good quality of washed gravel was available at a price delivered on the street of about $2.20 per cu yd. Gravel is, however, rather unsuitable for use in making a wearing surface which depends on bituminous cement for its bond. The reason for this is that gravel, being generally round and weather-worn, does not lock well together, and the strength of the wearing surface is dependent almost entirely on the bond of the bituminous cement. It was necessary, however, to decide which was to be preferred under the circumstances. The limestone had better locking qualities, but was high in first cost, and the amount of money available was limited. It was decided therefore to use the gravel and make every effort to lock or bond it by rolling.

"It was specified that the gravel, as spread on the street, should be of a size that would pass a ring of 2-in diameter and be held on a ring of ½-in diameter. After a small yardage had been spread under these specifications, it was found that there was no lock at all between the stones, and that when filled with the bituminous cement but little strength was secured. This yardage was taken up and the gravel afterwards used was still further screened so as to eliminate practically all pebbles below ¾ in in size. After the surface had been rolled to the satisfaction of the inspector, 1½ gal per sq yd of Texaco asphalt was poured over the pavement, and, immediately behind the asphalt, pea-size gravel was lightly spread over the surface, and the whole rolled again. This was then covered with ½ to ¾ gal per sq yd of asphalt cement, and over this second coat of cement was spread coarse sand, and the whole again rolled.

"On account of the fact that so much care had to be taken with the gravel used, and that it all had to be screened after being received in order to eliminate small pebbles which prevented the locking together of individual stones, it would probably have been cheaper to have purchased crushed limestone in the first place. Some conclusions may be drawn as to this method of construction. They are as follows: Gravel can be made to lock and bond only after a great deal of labor and trouble are taken with it. It would probably be economical to pay twice as much for crushed stone as for gravel to get equal results."

11. Specifications for Construction

The fundamental characteristics of methods of construction, A to F, under which the following specifications are classified, are described in Art. 10.

Method A. The 1917 Dallas, Texas, Specifications are as follows:

"**Asphalt Macadam Wearing Surface.** Upon this foundation crushed Jacksboro

limestone, 1½ to ⅜ in in size, shall then be evenly spread to such thickness that after thoroly rolling with a 10-ton roller it shall conform with the grade of the completed street.

"Asphalt, heated by means of an improved form of heater, to a temperature of not less than 149° C (300° F) and not more than 204° C (400° F), shall then be applied by means of an approved distributing device, which will spread the asphalt over the surface in the proper quantity. Twenty pounds of asphalt shall be used to each square yard of surface. No asphalt shall be applied to the street surface when the stone is wet, nor when the temperature of the air is less than 15° C (60° F).

"Hot crushed Jacksboro limestone chips shall then be evenly spread over the street surface, rolled until cool and the entire street surface conforms to the true grade and cross-section of the completed street."

Method B. Am. Soc. Mun. Imp. 1917 Specifications. For sections covering broken stone, see Art. 6; for sections covering bituminous cements, see Art. 8.

" General Description. The bituminous macadam pavement shall consist of three courses of broken stone, separately constructed, laid to conform to the required grades and cross-sections, and constructed as hereinafter specified with bituminous material incorporated with the top or third course.

" First Course. After the subgrade or subbase course shall have been prepared as specified, a course of No. 4 broken stone shall be evenly spread so that it shall have, after rolling, the required thickness of 3½ in. The depth of loose broken stone shall be gauged by the use of strings between iron stakes, as directed. The spreading of the broken stone must be from piles dumped on boards provided for the purpose or from piles dumped alongside the road, or as directed by the Engineer. This course shall be thoroly rolled with a 12 to 15-ton road roller. The initial rolling shall begin at the sides of the road and continue towards the center and shall be kept up until the stone is keyed together and there is no disturbance of the stone ahead of the roller. After the first course has been compacted, it shall be evenly covered with a thin layer of screenings. The quantity of screenings to be used shall be just sufficient to cover the larger stones and care shall be exercised to avoid the use of an excess of the screenings. This covering shall then be rolled as heretofore provided except that water shall be used in connection with the rolling as follows: After the screenings shall have been lightly rolled, water shall be sprinkled on the road surface just ahead of the roller, in such quantity as will prevent the sticking to the wheels of the roller of the fine material on the surface, and the combined spreading of screenings, watering and rolling shall be continued until the voids of the broken stone become so filled with the finer particles as to result in a wave of grout being pushed along the road surface by the front wheel of the roller. After the completion of the rolling, no teaming other than that necessary for bringing on the broken stone for the next course shall be allowed over the rolled broken stone. Should it be apparent after the rolling of the first course that the subgrade material shall have become churned up into or mixed with the broken stone of this course, whether by reason of the rolling, or by hauling over the broken stone or otherwise, the contractor shall at his own expense remove and replace such mixture of subgrade material and broken stone with clean broken stone of the proper size and shall roll the material to produce a uniform, firm and even first course as required.

" Second Course. On the completed first course shall be spread, in the manner specified in the preceding paragraph, No. 4 broken stone to form the second course. This broken stone shall be evenly spread to such a depth that it shall have, after rolling, the required thickness of 3½ in. The second course shall be compacted, puddled with screenings and water, and finished under the same provisions as prescribed for the first course. When the rolling shall have been completed, the surface of the second course shall be firm, even and true to the lines, grades and cross-sections. If the surface is not slightly rough so as to afford a sufficient mechanical bond for the third course, it shall be broomed.

" Description of Top Course. The top course of the bituminous macadam pavement shall consist of a third course of broken stone and two applications of bituminous material, each application being followed by the distribution of a layer of No. 1 broken stone, constructed as hereinafter specified.

"**Asphalt Cement and Refined Tar.** The asphalt cement or refined tar, hereinafter referred to as bituminous material, used in the construction of the third course of the bituminous macadam pavement shall conform with either one of the specifications covering the chemical and physical properties of bituminous materials included under the item entitled 'Asphalt Cements and Refined Tars for Bituminous Macadam Pavement.' See Art. 8.

" **Heating Bituminous Materials.** Bituminous materials shall be heated in kettles or tanks so designed as to admit of even heating of the entire mass, with an efficient and positive control of the heat at all times. Asphalt cement shall be heated as directed by the Engineer to a temperature between 135° C (275° F) and 177° C (350° F). All asphalt cement heated beyond 177° C (350° F) shall be rejected. Refined tar shall be heated as directed by the Engineer to a temperature between 93° C (200° F) and 121° C (250° F). All refined tar heated beyond 121° C (250° F) shall be rejected. No tar shall be heated in kettles or tanks containing any oil or asphalt cement. Before changing from one type of material to another, kettles or tanks shall be scrupulously cleaned in order to avoid mixtures of the two. Any mixtures of different kinds of bituminous materials shall be rejected.

" **Thermometers Furnished by Contractors.** The contractor shall provide a sufficient number of accurate, efficient, stationary thermometers for determining the temperature of the bituminous material in kettles or tanks.

" **Third Course of Broken Stone.** On the completed second course, when thoroly dry, shall be spread, in the manner above specified for the first course, dry No. 3 broken stone to form the third course. This broken stone shall be evenly spread to such a depth that it will have, after rolling, the required thickness of 2½ in. The third course shall be thoroly compacted by dry rolling until the fragments of broken stone have keyed together in accordance with the same provisions covering rolling as prescribed for the 'First Course.'

" **First Application of Bituminous Material.** After the third course of broken stone shall have been thoroly compacted as specified and when clean and thoroly dry, the bituminous material shall be uniformly applied over the prepared surface of the third course by means of a pressure distributor as hereinafter specified. The asphalt cement, when applied, shall have a temperature between 135° C (275° F) and 177° C (350° F). The refined tar, when applied, shall have a temperature between 93° C (200° F) and 121° C (250° F). The total amount of bituminous material to be used in the first application shall not be less than 1½ gal nor more than 1¾ gal per sq yd, the precise quantity being determined by the Engineer.

" **Pressure Distributor.** See Art. 9.

" **First Application of No. 1 Broken Stone.** Immediately after the application of the bituminous material, a layer of dry No. 1 broken stone, not to exceed ⅜ in in thickness, shall be spread as directed by the Engineer over the surface of the bituminous material and shall be at once rolled as directed by the Engineer with a roller weighing between 12 and 15 tons. During the rolling process, additional No. 1 broken stone shall be applied and broomed until the voids in the upper portion of the third course are filled to the satisfaction of the Engineer.

" **Second Application of Bituminous Material.** Prior to the second application of bituminous material, all loose No. 1 broken stone shall be swept from the surface of the pavement. When thoroly clean and dry, a second application of bituminous material shall be uniformly applied over the surface by means of a pressure distributor as specified above. When applied the asphalt cement shall have a temperature between 135° C (275° F) and 177° C (350° F). When applied the refined tar shall have a temperature between 93° C (200° F) and 121° C (250° F). The total amount of bituminous material to be used in the second application shall not be less than ½ gal nor more than ¾ gal per sq yd, the precise quantity being determined by the Engineer.

" **Second Application of No. 1 Broken Stone.** Immediately after the second application of bituminous material, a layer of dry No. 1 broken stone, not to exceed ⅜ in in thickness, shall be spread and broomed as directed by the Engineer over the surface of the bituminous material and thereafter at once rolled as directed by the Engineer with a roller weighing between 12 and 15 tons. The rolling shall be continued and additional No. 1 broken stone shall be applied until a smooth, uniform surface is produced to the satisfaction of the Engineer.

"**Seasonal and Weather Limitations.** No bituminous material shall be applied when the air temperature in the shade is below 10° C (50° F), except by the written permission of the Engineer.

"**Measurement and Payment.** The quantity of bituminous macadam pavement to be paid for under this item shall be the number of square yards, measured horizontally, satisfactorily completed in accordance with the specifications. The price stipulated in this item shall include the furnishing, crushing and screening of the different sizes of broken stone, the heating and distributing of the bituminous material, and all materials, work and expenses incidental to the completion of the bituminous macadam pavement except the furnishing of the bituminous material, which will be included for payment under the item entitled Asphalt Cements and Refined Tars for Bituminous Macadam Pavements." See Art. 8.

Method B. The 1917 Penn. State Highway Dept. Specifications are as follows:

"**Crushed Stone.** The stone shall be first quality, cubical crushed rock, free from dirt, dust and foreign materials and of such size as shall pass a 3-in revolving screen and be retained on a 1-in screen. No intermediate sizes shall be removed. The French coefficient of wear shall be not less than 10. For filling the surface voids in the above described stone after the bituminous material has been applied, hard, tough crushed rock, free from dirt, dust and foreign materials, passing a 1-in revolving screen and being retained on a ½-in screen and having a French coefficient of wear of not less than 15, shall be used. This stone is known as ¾-in material.

"**Stone Chips.** The stone chips shall be of the best quality rock and of such sizes as shall pass a ⅝-in screen, with the larger sizes predominating and shall be free from dirt, dust and foreign materials. The French coefficient of wear shall be not less than 15.

"**Placing.** The broken stone shall be spread upon the base course, with shovels, from piles alongside the roadway or from a dumping board. In no case shall the broken stone be dumped directly upon the base course. The depth of the surface course shall be not less than 3 in at any point after final compression. If a greater depth is laid by the contractor no extra allowance for such additional depth will be made.

"**Rolling.** After the broken stone for the surface course has been laid true to line, grade and cross-section, it shall be rolled with a power roller, weighing not less than 10 tons, until the stone is compressed to a firm, even surface, but not to final compression.

"**Bituminous Application.** After the rolling has been completed as above there shall be spread evenly over the surface a quantity of approved bituminous binder, not less than 1¼ nor more than 1½ gal, as directed, to each sq yd of surface area. The bituminous material shall be heated to and applied at a temperature of not less than 107° C (225° F) nor more than 163° C (325° F), if an asphalt, and not less than 79° C (175° F), nor more than 121° C (250° F), if a tar product, as may be directed. After the bituminous binder has been applied, there shall be spread a layer of ¾-in dry crushed rock free from dust and in such quantity as just will cover the surface and fill the surface voids. Rolling then shall continue until the surface is bonded thoroly.

"**Seal Coat.** After the surface has been prepared as above, it shall be swept clean of all loose stone and an application of bituminous binder of approximately ⅓ to ½ gal, as directed, to the sq yd of surface area shall be applied evenly, which shall be covered immediately with a thin layer of dry stone chips and rolled lightly. The quantity of chips shall be sufficient to take up all excess bituminous material remaining on the surface. The finished surface shall conform with the grade and cross-sections.

"**Weather Conditions.** No bituminous materials shall be applied unless the stone surfacing is thoroly dry and the air temperature is at 18° C (65° F) or above."

Method C. The 1917 Ohio State Highway Dept. Specifications are as follows:

"**Sizes of Aggregate.** No. 1. Material passing thru a 3½-in and retained on a 2-in opening. No. 1 size for stone with an abrasion loss of greater than 6%, shall consist of material passing thru a 4-in and retained on a 2½-in opening.

No. 2. Material passing thru a $2\frac{1}{2}$-in and retained on a $1\frac{1}{2}$-in opening.

No. 3. Material passing thru a $1\frac{1}{2}$-in and retained on a $\frac{3}{4}$-in opening.

No. 4. Grit. Material passing thru a $\frac{3}{4}$-in and retained on a $\frac{1}{4}$-in opening.

No. 6. Grit. Material passing thru a $\frac{1}{2}$-in opening and retained on a $\frac{3}{16}$-in opening or square mesh.

No. 7. Screenings. Material passing thru a $\frac{1}{4}$-in opening or square mesh and containing not more than 30% of material that will pass a 100-mesh sieve."

"Size of Aggregate for Top Course. If the thickness of the completed top course is 3 in or less, No. 2 size aggregate shall be used. For courses over 3 in in depth, No. 1 size aggregate shall be used.

"Spreading Coarse Aggregate. Upon the foundation, prepared as elsewhere described, shall be spread a course of stone or slag, of sufficient depth to roll to the finished thickness shown on the plans. Cubical blocks of wood, or side and center guide forms of proper size, shall be used to fix the depth of the loose material. In spreading, care must be taken to preserve the grade and crown, and also to prevent a wavy surface. After the stone or slag is spread upon the foundation, it shall be harrowed to aid in producing a uniform and even surface. Any thin, flat or oversize stones that appear on the surface at any time during the process of construction, shall be removed therefrom. When spread, the material shall have a uniform distribution of sizes thruout the entire course.

"Rolling. The top course shall be rolled until it is thoroly compacted and the surface is smooth and conforms to the established grade and cross-section. The rolling shall begin with the outside driver covering equal parts of the metal and shoulder, and the roller shall be run forward and backward along the edge of the metal until the shoulder and metal are firmly bound together. The rolling shall then progress gradually from each side toward the center and this process repeated until the entire course has been thoroly rolled. Any low places that develop during the rolling shall be loosened and then refilled with the same kind of material as that of which this course is constructed, and again rolled, as required above.

"Partial Filling. Where this top course is to be thicker than 3 in, when completed, the bottom voids up to within 3 in of the surface shall be filled with dry No. 7 limestone or slag screenings or dry sand. The screenings shall be applied thinly over the surface during the process of dry rolling. The stone shall be so treated that the upper 3 in of the course will be free from all dust and fine material when the bituminous material is applied. During the finishing process of rolling any large voids in this course shall be partially filled with No. 3 stone which shall be whipped into the voids with shovels or by hand. Rolling shall be continued during the application of the stone. The voids in this top course shall be just sufficiently filled so that the amount of bituminous material specified will fill the remaining voids and produce a dense surface when the road is completed. Any dust remaining on the surface stone shall be removed by sprinkling with water. Sufficient time for the stone to dry shall elapse before any bituminous material is applied, but there shall be no more than 1000 ft of top course uncompleted at any one time.

"Applying Bituminous Material. No bituminous material shall be applied when the temperature of the atmosphere on the work is below 7° C (45° F) or when the stone is damp or wet. Without disturbing the stone or grit placed and rolled as above described, the bituminous material, of the quality specified in the estimate, shall be uniformly applied to the surface by means of approved pressure distributors or hand sprinkling pots. The total quantity of bituminous material used, including the seal coat, shall be as specified in the estimate. Immediately after the bituminous binder is applied, there shall be evenly spread over the entire surface, hard, clean, No. 4 grit of stone, slag or gravel in amount sufficient to fill the surface voids. The grit shall be evenly distributed with a push broom to insure the filling of the voids. It shall be so applied as to leave a minimum amount of grit on the surface. The road shall then be thoroly rolled before the bituminous material stiffens enough to prevent the grit from being readily incorporated with it. The rolling shall continue until a firm and smooth surface results, conforming to the requirements of the plans. Any surplus loose grit not held by the bituminous material shall be swept off and the surface kept clean until the seal coat is applied.

"Bituminous Seal Coat. After this rolling, not less than $\frac{1}{2}$ gal of the same bituminous material, heated as above, shall be uniformly spread over each square yard,

and the surface again covered with No. 4 or No. 6 grit at the rate of about 1 cu yd to 70 sq yd of surface. The road shall then be rolled until thoroly compacted. A sufficient amount of grit shall be left on the surface to protect the road while setting up."

Method D. The Road Board of England General Directions for Surfacing with Pitch-Grouted Macadam are as follows:

"1. Any road which is to be surfaced with pitch-grouted macadam should have a proper foundation or sub-crust of adequate thickness to bear the traffic likely to use it.

"2. Before laying a new surface of pitch-grouted macadam the thickness of the old crust, including foundations, should be ascertained by opening trial trenches at intervals averaging about 150 yd extending from the haunch of the road to the center, such trenches to be made alternately on opposite sides of the road.

"3. The thickness of the surface coating of pitch-grouted macadam when finished and consolidated by rolling should be 2½ to 3 in, except on very light traffic roads, when the thickness may be 2 in for single-pitch-grouting, and from 4 to 4½ in for the double-pitch-grouting hereafter described.

"4. In the case of naturally hard subsoils, not materially softened by infiltration of surface water, the total thickness of the road crust, including foundation, if any, after consolidation by rolling of the new pitch-grouted surface, should not under ordinary circumstances be less than 6 in, unless the subsoil is so hard as in itself to act as a good foundation, in which case the thickness of the road crust may be reduced to 4 in. In the case of clay or other yielding subsoils the total thickness should not be less than 11 in.

"5. The finished surface should have a cross-fall of about 1 in 32. If the crust is not sufficiently thick at the crown to enable this cross-fall to be obtained with a new coating of the thickness above mentioned, then the old surface should be left intact and unscarified, and the thickness of the new pitch-grouted coating increased as far as may be necessary. If the crust is of sufficient thickness for the purpose, the regulation of the cross-fall should be carried out by scarifying the surface and removing material from the crown to the sides previous to the application of the new coating. Material loosened by scarifying should be screened and all material finer than ½ in should be thrown aside.

"6. The aggregate of broken stone to form the new surface of pitch-grouted macadam should contain broken stone of approved quality of which at least 60% must be broken to the size of 2½ in, and 35% to sizes graded from 2½ to 1¼ in. In addition to this 5% of chippings of the same stone, varying from ¾ in down to ⅜ in, should be used for closing after the grouting with melted pitch.

"7. For making pitch-grouted macadam, the pitch used should comply with the Road Board Specification for Pitch (see Art. 8), its viscosity being altered to suit climatic and local conditions by varying the quantity of the tar oils as specified therein.

"8. It is important that the pitch should not be poured if the surface of the stone is wet. The stone may be protected by tarpaulins, or, if wet, may be dried *in situ* by portable blowers or other means.

"9. The quantity of pitch required to grout a single coating is approximately, for a consolidated thickness of 2 in, 1¼ gal per yd super, for 2½ in, 1½ gal per yd super, and for 3 in, 2 gal per yd super, but these quantities may vary with different materials and care must always be taken to fill the voids adequately.

"10. The aggregate after having been spread and levelled must be rolled down dry until the surface is formed, but without the addition of any small material.

"11. The pitch, after being carefully melted as described in Clause 18, must be raised to a temperature of 149° C (300° F). Clean, sharp sand must be heated on sand heaters to a temperature of 204° C (400° F). A dandy, or portable mixing vessel, is then to be filled with equal parts, by measurement, of the heated pitch and the hot sand, and the mixture, hereafter called the matrix, is to be kept well stirred, while it is being emptied from the dandy or portable mixing vessel into pouring cans of from 2 to 3 gal capacity, which are used for pouring the matrix on to the roadway. Not only during the process of mixing but afterwards, right up to the time of actual pouring, the matrix must be kept well stirred. The matrix prepared with pitch in the quantities specified in Clause 9 should be sufficient to fill the voids of the aggregate.

"12. The final rolling should be commenced immediately after pouring the pitch matrix, and carried on rapidly before the matrix has time to set. The 5% of graded chippings should be spread over the grouted surface in part previously to and the remainder during the process of rolling. The traffic may be allowed on to the finished surface as soon as the surface has cooled to the normal temperature.

"13. Double Pitch-Grouting. When the traffic is so heavy that a consolidated thickness of from 4 to 4½ in of pitch-grouted macadam is required, it is desirable, in order to obtain the best and most economical results, to divide the coating into two layers, the bottom layer to be the thicker one and to consist of large stones, the two layers being rolled down and grouted separately. Any local stone which can be procured cheaply may, if suitable in quality for foundation work, be used for the bottom layer graded from 3-in gauge down to 2-in gauge. No chippings are required for finishing the rolling of the bottom layer. The aggregate for the upper layer should consist of hard road stone of approved wearing quality, broken to 1½-in gauge, and 5% of chippings of the same stone used for the upper layer, graded from ½-inch down to ¼-in, should be added before and during the process of rolling, and rolled down so as to form the finished surface of the road.

"14. In pouring the pitch on the bottom layer the surface of the pitch should not be brought to the surface of the stone, but should lie about ½ in below such surface, with the object of providing a key for the upper layer.

"15. The materials and the methods of grouting and laying down in the case of double-pitch-grouting, should, except when otherwise expressly stated, conform to the provisions of Clauses 7, 8, 10, 11 and 12.

"16. The quantity of pitch required for double-pitch-grouting is approximately, for a consolidated thickness of 4 in, 3¼ gal per yd super, and for 4½ in, 3½ gal per yd super, but these quantities may vary with different materials, and care must always be taken to fill the voids in the surface coating adequately.

"17. For the purpose of accurately ascertaining the proportions necessary for the matrix, it is essential that portable weights, scales and measures be provided, and all materials used in the preparation of the matrix should be accurately proportioned by weight or measurement.

"18. Instructions for Melting the Pitch. The pitch boilers of from 2 to 3 tons capacity should be charged with pitch and about one-half of the proper proportion of tar oils. The fire should then be lighted, and thereafter a steady fire, with fire doors closed, should be maintained, when, in from 4 to 5 hr, the pitch should be thoroly melted. A bright fire should be kept until the pitch reaches a temperature of 149° C (300° F), when the remainder of the oils should be added and the mixture thoroly stirred; the fire-doors should then be opened and the temperature of the melted pitch permitted to fall to 121° or 132° C (250° or 270° F). The pitch should then be ready for use and in all cases should be thoroly well stirred before being drawn off. In the event of bad weather stopping the work of grouting the fire-door should be left open, the damper closed, and the temperature of the pitch allowed to fall to 93° C (200° F). It can be kept at this temperature for long periods with banked fires consuming about 7 lb of coke per hr. It is recommended that a suitable Fahrenheit thermometer with metal protection should be at hand to indicate the temperature of the melted pitch. Whenever the weather is favorable for the recommencement of the work the pitch must be again raised to 132° C (270° F) by closing the doors and sharp firing. It is desirable that the boiler should be kept air-tight when the pitch is being melted, by the use of air-tight covers properly packed so as to make an air-tight joint."

Method D. The Mass. Highway Comm. Specifications (24) are as follows:

"Upon the lower course shall be spread the upper course of stone, which shall consist of broken trap rock that will pass thru a ring 2½ in in diameter and will not pass thru a ring 1¼ in in diameter, and shall be 2 in in thickness after rolling with a steam roller, and evened up with material of the same size and quality as has been used in that particular course and to the satisfaction of the Engineer.

"Upon and into the interstices of the upper course, prepared as hereinbefore described, shall be broomed and poured hot tar and hot sand at the rate of 2½ gal per sq yd.

"The proportions of sand and tar in the mixture shall be equal in volume, that is, the mixture shall consist of 50% hot sand and 50% hot tar. The sand shall be clean and sharp and free from loam, clay and adventitious matter of all kinds. The grains of sand shall pass thru a 16-mesh sieve, not more than 20% shall pass a 100-mesh sieve, not more than 5% shall pass a 200-mesh sieve. The sand shall be heated in a manner satisfactory to the Engineer to approximately 149° C (300° F), and after heating, the sand shall be mixed immediately with the tar, in such manner as to be satisfactory to the Engineer, and so handled that when it is poured into the road, the sand will not have settled to the bottom of the tar, but shall be in complete suspension. Before mixing, the tar shall have been heated to a temperature approximately 107° C (225° F).

"Immediately after the tar and sand mixture has been broomed and poured into the top course the surface shall be covered with a thin layer of pea stone and immediately rolled with a steam roller weighing not less than 10 tons, to the satisfaction of the Engineer."

Method E. Specifications Based upon American Practice.

Base Course. The lower course shall consist of crushed stone which shall pass a 3½-in ring and be retained on a 2¼-in ring, spread to a finished depth of 4 in, but 2½ in below the finished grade. The course shall be filled thoroly with sharp sand, gravel, stone screenings or similar filler approved by the engineer, and rolled until smooth and firm. No filler shall be left on the surface.

Sand Layer. On this course of stone thus prepared, shall be spread evenly a layer of sharp sand to the depth of not less than ¾ in, nor more than 1 in.

First Coat Tar. Refined tar, heated to a temperature of not less than 93° C (200° F) and not more than 135° C (275° F), shall then be spread evenly over the surface to the amount of not less than 1 gal, nor more than 1¼ gal per sq yd.

Wearing Course. The wearing course shall be placed on the tar mortar and shall consist of a layer of crushed stone which shall pass a 2¼-in screen and be retained on a 1¼-in screen spread to a finished depth of not less than 2½ in. This size of stone is best for trap rock or other hard rock which does not break under the roller. If limestone or other soft rock is used a larger sized stone may be used to advantage. This course shall not be filled, but shall be keyed thoroly together by rolling. The surface shall be left smooth and of even firm texture clean and free from dirt, clay, stone dust or other material which will prevent the easy penetration of the refined tar.

Second Coat Tar. Refined tar, heated to a temperature of not less than 93° C (200° F) and not more than 135° C (275° F) shall be spread uniformly over the surface when dry to the amount of not less than 1½ gal, nor more than 1¾ gal per sq yd.

Three-Fourths Inch Stone. As soon as possible after spreading the refined tar ¾-in crushed stone without dust, stone which shall pass a 1¼-in screen and be retained on a ½-in screen, shall be spread over the surface filling the voids, but leaving no surplus on the surface. The road shall then be rolled until firm.

Seal Coat. The road shall be swept free from any particles of stone not held by the tar. Not less than ½ nor more than ¾ gal of refined tar per sq yd, heated to a temperature of not less than 93° C (200° F) nor more than 135° C (275° F), shall be spread over the surface and covered with stone screenings or sharp sand. The road shall then be rolled until compacted. A sufficient amount of screenings or sand shall be left on the surface to protect the road while setting up.

Method F. The 1917 Specifications of the Ill. State Highway Dept. are as follows:

"**Tests and Sizes of Crushed Stone.** Crushed stone should be of sound and durable material, and shall have a coefficient of wear according to the Duval test of not less than 7. The sizes of crushed stone that shall be used are as follows:

1. Uniformly graded and broken to a size that will pass over a 2-in ring and will just pass thru a 3-in ring, which size will hereinafter be referred to as 3-in stone.

2. Uniformly graded and broken to a size that will pass over a ¼-in square mesh and will just pass thru a ½-in ring, which size will hereinafter be referred to as chips. This stone shall be clean and entirely free from dust.

3. Uniformly graded and broken to a size that will just pass thru a ½-in ring and be uniformly graded to dust. This material will hereinafter be referred to as screenings.

" **Spreading First Course of Stone.** The first course of stone shall be of 3-in stone, spread to compact under rolling to the dimensions shown on the plans. The stone may be dumped directly upon the roadbed, but in such case it shall be distributed uniformly over the foundation.

" **Harrowing First Course of Stone.** After the first course of stone has been spread, it shall be thoroly harrowed several times over until a maximum density is obtained and all fine material which may have been mixed with 3-in stone has been shaken to the bottom of the layer. The harrow shall be of the stiff tooth type and shall have metal teeth at least 1 in in diameter extending 6 in below the harrow frame. The spacing of the teeth shall be such as to admit the free passage of all stone between them, and yet so displace the stone as to produce the density desired. The design of the harrow shall provide a weight of from 8 to 12 lb upon each tooth.

" **Rolling First Course of Stone.** After the stone for the first course has been spread to the required depth, harrowed, and then shaped to the proper cross-section, it shall be rolled until the entire surface is covered and thoroly compacted, forming a firm smooth surface. The rolling shall begin at the sides and work toward the center, at each rolling allowing an overlap of one-half of the width of one of the rear wheels, and these wheels shall cover the entire metal surface thoroly. The speed of the roller shall not exceed 100 ft per min. If any unevenness or depressions appear during or after rolling, material shall be added and rolled until there has been formed a thoroly compacted and uniform surface.

" **Spreading Screenings, Watering and Rolling.** After the first course of stone has been properly shaped and rolled to the satisfaction of the engineer, the screenings, or bonding gravel, shall be applied in several successive layers and the surface broomed and rolled between each application until the voids in the stone are practically filled with dry screenings. Screenings shall be spread uniformly over the surface of the road from piles along the side, and in no case shall screenings be dumped directly upon the surface of the stone. After the voids have been filled with screenings, the surface shall be sprinkled until saturated, the sprinkler being followed by the roller, and more screenings shall be added, if necessary. The sprinkling, sweeping and rolling shall continue until a grout has been formed that will fill all of the voids and will form a wave of water and grout before the wheels of the roller. The entire operation of spreading screenings, watering and rolling shall be done to the satisfaction of the engineer.

" **Spreading and Harrowing Second Course of Stone.** The stone for the second course shall not be spread until the foundation or first course has been completed and shoulders made as herein specified. The second course shall be of 3-in stone, and shall be spread to compact under rolling to the dimensions shown on the plans. After the second course has been spread it shall be harrowed as hereinbefore specified for the first course of stone.

" **Rolling Second Course of Stone.** After the stone for the second course has been spread to the required depth, harrowed and shaped to the proper cross-section, it shall be rolled until it is compacted and forms a firm, smooth surface. The rolling shall begin at the sides of the pavement and work toward the center, and, when completed, the surface of the shoulders, and of the second course, shall be smooth and true to the cross-section shown on the plans. If any unevenness or depressions appear during or after rolling the second course, either on the surface of the shoulders or stone, material shall be removed, or additional material shall be added to correct all such unevenness or depressions, and the entire surface rolled until it becomes smooth and uniform in character.

" **Spreading First Coat of Bituminous Binder.** After the surface has been prepared as described above and it is dry and free from dust, the bituminous binder heretofore specified shall be uniformly distributed at the approximate rate of 1½ gal per sq yd of surface. It shall be spread at the temperature hereinbefore prescribed and in a manner which will insure a uniform appearance to all parts of the surface. If the surface of the road is open and the stones are not tightly keyed after rolling as prescribed above, the surface voids shall be partially filled with chips before the bituminous binder is applied.

" **Spreading First Course of Chips.** After the first course of bituminous binder has been applied, the surface voids shall be filled with chips which shall be whipped into the

surface from shovels, the quantity being such as will just fill the surface voids. After the chips have been whipped and broomed into the surface and all surface voids filled, the excess material remaining on the surface shall be swept off the pavement and the surface rolled once over with the roller.

"**Spreading Second Coat of Bituminous Binder.** After the first course of chips has been spread and brushed into the surface and rolled slightly, a second coat of the bituminous binder shall be spread at the approximate rate of ⅓ gal per sq yd of surface. The binder shall be applied hot and in such manner as will insure a uniform appearance of the surface.

"**Spreading Second Course of Chips or Torpedo Gravel.** After the second coat of bituminous binder has been applied, there shall be spread a thin course of chips or torpedo gravel which shall be brushed into the surface. If after these voids are filled, there is any excess of stone chips or torpedo gravel on the surface, it shall be brushed to the edge of the pavement. The surface shall then be rolled until it is entirely free from depressions, waves, etc, the wheels being wet to prevent sticking. After the surface has been rolled, it shall be allowed to stand for at least ½ day before being open to traffic. After being open to traffic, if during the first 30 days the bituminous binder exudes on any part of the surface, such places shall be covered with torpedo gravel or chips in a sufficient quantity to absorb the excess binder."

Method G. 1917 Specifications of Oakland, Cal. For sections covering broken stone, see Art. 6; for sections covering the asphaltic oil employed, see Art. 8.

"**Wearing Course.** Upon the base course shall be spread a course of broken stone, to be known herein as the top course, having a uniform depth of 3 in, measured before rolling. This top course shall then be sprinkled uniformly with oil at the rate of ½ gal per sq yd of street surface covered, after which said top course shall be harrowed and again sprinkled uniformly with oil at the rate of ½ gal per yd of surface covered. This oiled surface shall then be thoroly rolled until said top course is firm and uniform, screenings being spread in light layers on said top course during the rolling. After the top course has been so prepared, oil shall be sprinkled uniformly over the surface at the rate of ½ gal per sq yd of street surface covered. This oil shall be permitted to penetrate into the top course, after which the roadway shall be screened and rolled and swept until the voids are filled and the pavement is firm and uniform. The pavement shall then be treated with another application of oil at the rate of ½ gal per sq yd, then screened, rolled and swept until all of the oil has been absorbed and the surface is uniform and firm.

"**The Rolling** herein specified shall be done with a self-propelled roller weighing at least 300 lb per lin in width of tread. In all of the hereinabove mentioned rolling, the sides of the roadway shall be rolled first, the roller gradually working toward the center of the roadway.

"Oil shall be applied to the pavement under pressure of at least 30 lb per sq in. The appliance used for said oiling shall be capable of spraying the pavement in strips at least 8 ft wide and shall, in addition to being provided with the necessary nozzles for spraying such strips, be also provided with a hose, with spraying nozzle attached thereto, for the purpose of spraying portions of the pavement inaccessible to the regular oiling device. All oil must be delivered at the point required for sprinkling at a temperature of not less than 121° C (250° F). All of the above-mentioned oiling shall be done while the atmospheric temperature is above 18° C (65° F), or when the sun is shining. No oiling shall be permitted when the layer of broken stone or the screenings are in any way wet."

12. Construction Cost Data

The cost of bituminous pavements, built by penetration methods, varies with the amount and kind of bituminous material and road metal used, and the method of construction employed. An average cost, using 6 in of compacted broken stone and a total of 2 to 2¾ gal of bituminous material per sq yd, varies from 25 to 40 cents per sq yd in excess of the cost of water-bound broken stone roads, or from 70 cents to $1.25 per sq yd.

Table I.—Cost of Bituminous Macadam Pavements in 1915 in Several Cities

From *Engineering and Contracting,* April 5, 1916

City	Square Yards	Price* per Square Yard	Total Thickness Inches	Kind of Binder
Bennington, Vt....	1 280	$0.70	6	Asphalt
Boston, Mass......	177 093	0.75	6	Tar
Springfield, Mass...	95 907	0.89†	6	Tar
Providence, R. I...	18 012	1.27	8 2/8	Tar
Oswego, N. Y......	15 832	1.58	8	Asphalt
Pittsburgh, Pa.....	8 920	1.55	9 1/2	Tar
Cincinnati, O......	5 106	1.15	9	Tar
Toledo, O..........	5 489	1.40	10	Tar
Chicago, Ill.......	598 254	1.21†	10 1/2	Asphalt
Milwaukee, Wis...	8 890	1.08†	8 1/2	Tar
St. Paul, Minn....	3 600	1.25	7	Tar
Springfield, Mo....	9 966	1.06	6	Asphalt
Durham, N. C.....	20 900	0.90†	6	Asphalt
Covington, Ky....	15 000	1.20	10	Tar
Fort Worth, Tex...	5 267	1.27	6	Asphalt
Riverside, Cal.....	36 850	0.78	4	Asphalt

*Price covers pavement, foundation, and grading.
†Does not include grading.

Bituminous Macadam Pavement Cost Data by Ill. Highway Comm. (40b). Length, 1500 ft; area, 3500 sq yd; thickness, 3 in; labor, 25 cents per hr; teams, 50 cents per hr; average haul, 1/2 mile; bituminous binder, 2.54 gal per sq yd; constructed, Sept. 29 to Nov. 25, 1915.

Bituminous Macadam Pavement Constructed with Pouring Cans, Alexandria, Va. Cost Data compiled by E. C. Dunn, City Engineer (28). For description of method of construction, see Art. 9. "The cost for an average square yard exclusive of grading was $1.01 in 1915 and $1.135 in 1916, the difference being due to increased cost of material in 1916. The details of the average cost per square yard in 1916 were as follows:

Cost of Labor and Materials

	Per square yard
Superintendence and inspection	$0.077
Cost of stone and gravel	0.430
Cost of sand and chips	0.085
Cost of bituminous binder	0.217
Hauling stone, gravel and chips	0.210
Spreading stone and screenings	0.058
Rolling and sprinkling	0.039
Heating and applying bituminous binder	0.060
Incidental expense	0.019
Total cost	$1.195

Concrete Base

	Cents	Cents
Materials:		
Water	0.25	
Sand delivered 165 lb at 1/2 cent	8.25	
Cinders, on cars, 1/7 cu yd at 16 2/3 cents	2.38	
Cement, on cars, 11/100 bbl at $1.47	16.17	
Tools, etc	1.00	28.05
Labor:		
On concrete and placing 50 lb stone	13.00	
Teams	4.00	
Supervision	0.50	17.50
Total cost of concrete base		45.55

Top Wearing Surface

Material:	Cents	Cents
Stone 350 lb trap on cars at 0.69 cents	24.15	
Asphalt, 2½ gal on cars at 8.4 cents	21.00	
Fuel	0.80	
Tools, etc	2.00	47.95
Labor:		
Men	12.50	
Teams	6.00	
Supervision	1.50	20.00
Total cost of top wearing surface		67.95

Total cost of concrete base and wearing course per square yard, $1.135.

Wages: Foreman, 25 cents per hr; laborers, 17 to 18 cents; carts, 30 cents, and double teams, 40 cents per hr; haul, 0.95 mile, average. Work done by day labor, City Engineer's wages not included."

Bituminous Gravel Pavement, Longview, Texas. According to Green (37), the cost of constructing the bituminous gravel pavement described in Art. 9 was $1.40 per sq yd complete, details being given in Table II:

Table II

Quantities	Grading, Including Rolling, 1200 Cu Yd	Curb, Wood, 2 by 12 In 1915 Lin Ft	Foundations, 8 In Loose, 785 Cu Yd	Top Coat, Gravel, 404.3 Cu Yd	Asphalt 3872 Sq Yd
Cost:					
Labor	$587.130	$141.160	$434.010	$629.080	$346.960
Labor, per unit	0.489	0.074	0.112	0.162	0.090
Material	....	95.080	1393.600	888.580	1111.250
Material, per unit	....	0.050	0.360	0.230	0.287
Total	$587.130	$236.240	$1827.610	$1517.660	$1458.210
Total, per unit	0.489	0.124	0.482	0.392	0.377

Wages: Foreman, $5.50; engineer, $5 and $3.50; timekeeper, $3; water boy, $1; skilled labor, $2.50; labor, $1.75; teams, $4. Materials: Crushed rock, $1.50 per cu yd; gravel and sand, $1.87 per cu yd; asphalt, $20 per ton; lumber, $10 per M.

MAINTENANCE

13. Causes of Failure

The causes of failure of bituminous macadam and bituminous gravel pavements may be considered under the following heads, bituminous material and methods of construction.

Bituminous Material. Unfortunately many are the instances where unsuitable bituminous materials have been employed. Many engineers having charge of bituminous work do not appreciate the fact that different types of bituminous materials have entirely different physical properties and require entirely different treatment in use, altho they may have been purchased under one and the same specification covering chemical and physical properties. In some cases entirely unjustifiable combinations of materials are employed. For instance, in one case an asphalt of excellent characteristics was used for the first application, while for the second

application an asphaltic oil having decidedly solvent and fluxing properties was employed. Overheating of the material has likewise proved the cause of many failures, as the properties of the materials are sometimes changed and in many cases the materials are ruined.

Methods of Construction. Failure of the wearing course usually results if the foundation is poorly constructed or is inherently deficient in the strength required to carry the traffic to which the roadway is subjected, or if the sub-drainage is poor. Insufficient rolling of the wearing course has caused many failures. Others are due to the uneven distribution of the bituminous material, frequently caused by the improper use of hand-pouring pots and hand-drawn distributors. Many unsatisfactory bituminous macadam pavements result from the use of the improper sizes of broken stone. The use of small sizes of soft stone, which has crushed under heavy rolling, has resulted in a closed surface, thus preventing the necessary penetration of the binder. Failures due to the rapid formation of fine cracks caused by the rocking movement of the individual stones under traffic, finally resulting in ravelling and general disintegration, are of common occurrence. Segregation of sizes of stone preventing uniform penetration results in lean or weak spots in some cases and fat spots in others. In certain cases after a rain the construction has been carried on before the broken stone immediately below the surface has dried out. Many of the causes attributed to the failures of bituminous surfaces may likewise apply to bituminous macadam and bituminous gravel pavements.

Failures Due to Subgrade Conditions by Patterson (42). "A penetration pavement is more susceptible to failure by reason of subgrade troubles than are many other pavements. The reason for this susceptibility is explained in many ways, but it seems logical to attribute it to the inability of the pavement to withstand upward pressure locally applied by frost action and to the unavoidable large percentage of voids which have a weakening effect. Penetration work gives the best results when laid over a freely permeable soil. Sand and gravel are ideal sub-soils. A heavy soil of low permeability is as a rule disastrous to penetration work in New England latitudes unless special precautions are taken. In Rhode Island state work, an insulating layer of sand or gravel beneath the pavement is always employed where the existing soil lacks the requisite degree of permeability. A fill of wall or field stone is substituted for the gravel or sand where sub-drainage and foundations are both required. Drainage of certain soils is not as a rule sufficient in penetration work. Replacing of undesirable soils for a depth of from 6 in to 2 ft below the pavement proper with sand or gravel appears to be the most satisfactory method."

14. Methods of Maintenance

General Considerations. The maintenance of many bituminous macadam pavements requires covering spots with sand, gravel, or stone chips, where either an uneven distribution or an uneven penetration has caused an excess of bituminous material to exude on the surface. Places which disintegrate should be cut out with perpendicular sides and refilled with either a mixed aggregate or by building the hole up with successive layers of road metal and bituminous material, the former method, however, giving the better results. Light oils and light tars should never be used for repairing holes, as the patches thus formed will not be stable and hence will soon be displaced by traffic. At varied intervals it is economical to renew the bituminous surface on the pavement by using from ¼ to ¾ gal per sq yd of the proper type of bituminous material.

Continuous Maintenance Methods and Equipment. In considering the equipment required to accomplish continuous maintenance of bituminous

macadam pavements, the following factors and principles are essentials of economical and satisfactory maintenance.

1. Small failures of the wearing course, and the wearing away of the bituminous surface on comparatively small areas should be repaired immediately. Otherwise the rate of disintegration will be materially increased, the annual maintenance charge will be greater than necessary, and the surface will be unsatisfactory to the users of the highway.

2. Continuous maintenance should be conducted so that the highway may be at once opened to traffic without injury resulting to the repaired sections. For the repair of pot-holes, ruts, and other holes or depressions, this implies the use of bituminous materials which will set up more quickly than those which have been used in many cases. If practicable, the same type and grade of bituminous binder should be used as was employed in the original construction.

3. In order to obtain satisfactory results, the labor should be efficient and should be under the supervision of an engineer experienced in the construction and maintenance of all types of highways, and with all kinds of bituminous materials used in the area under his jurisdiction.

4. The intimate relationship between the methods and materials used in construction and the character of the maintenance is such that, to ensure success, the construction and maintenance of highways in a unit of area, or a certain mileage, should be under the supervision of one engineer.

To accomplish continuous maintenance economically and efficiently under the foregoing conditions, the flying squadron, operated under the direction of an engineer in charge of construction and maintenance of highways in the area covered, appears to be the logical solution. The equipment of such a squadron will naturally depend on local conditions, such as the mileage of highways to be maintained, their relative location, the types of surfaces and pavements, the kinds of bituminous materials used, the mileage under guaranty, etc.

As an example of a definite problem in continuous maintenance, take a county or a division of a State where a considerable mileage of bituminous surfaces and bituminous pavements has been constructed. Granted a well-maintained system, the work to be accomplished by a flying squadron would consist, first, of routine repairs, including filling all holes, ruts, and other depressions with bituminous concrete, using a type of aggregate and bituminous material suitable to each case (see Sect. 16, Art. 23), and second, applying bituminous materials to all areas which gave indication of being in such condition that they should be re-treated at once rather than wait until the whole surface required another application. It will be practicable in many cases for the flying squadron to repaint guard-rails and perform other routine repair work. Under such conditions, it is believed that the use of a motor truck properly equipped will prove most satisfactory.

The equipment to be carried by the motor truck for the special repair work outlined should include the following machinery and supplies: A stone heater and mixer; two heating tanks; a surface heater; a hand roller; small barrels of bituminous materials of different types and grades; storage boxes of small tools such as brushes, squeegees, tampers, cutters, pouring cans, irons, shovels, picks, and hoes; and storage compartments for paints for guard-rails, and road metal of several sizes. Altho a storage capacity for road metal is called for in this equipment, it should be noted that only a few cubic feet will be carried, because the maintenance work performed will be confined to the repair of small patches. Usually, it will be practicable to

reload a truck each day. The fixtures for the equipment described should be arranged so as to be readily removed, thus allowing the truck to be utilized for general hauling purposes.

The equipment recommended herein could be carried by a 5-ton truck, capable of traveling 12 miles per hr, and having a gasoline storage capacity for a run of 100 miles. A clear body of 7 by 15 ft would be available for the installation of the equipment. The cost of operation under normal conditions during an 8-hr day would vary from $10 to $20, covering wages of chauffeur, rent of garage, interest on first cost, maintenance charges, depreciation, insurance, tires, gasoline, oil, and grease.

Conclusions on Suitable Bituminous Materials for Maintenance by Sharples (16d). "In building country roads, it has been the practice in many cases to construct a tar-bound macadam road, and coat it with one of the heavy asphaltic oils or light asphalts put on hot. This practice has given excellent results in many cases, and has been established as a standard specification in some states, notably in Connecticut. Some very good work has been done in this way. In carrying out work under a specification of this kind, it is very important that the grade of oil or oil-asphalt be so heavy that it will not penetrate the tar-bound macadam, but will stay on top as a blanket layer. An oil light enough to penetrate the tar-bound road is sure to give bad results. The speaker knows of a number of roads of this type, which were well built and then treated with a light oil, while still presenting a porous top. They disintegrated completely within a year when subjected to heavy horse-drawn traffic, altho neighboring sections sealed with tar products remained in good condition. If, however, a proper grade of asphaltic oil is used, this disintegration will not occur.

"Under city or town traffic conditions, the tendency of an oil-asphalt top over a tar-bound macadam is to mush up and become soft under horse-drawn traffic in wet weather, due to the emulsifying effect of the water and organic material which collects on the asphalt top. When these conditions are to be provided for it is important so far as present experience indicates, to use only tar seal coats on top of the tar-bound macadam. The refined tars used for the seal coats are preferably somewhat softer than the tar used in the tar-bound macadam, but the subsequent treatment and care of the road modifies somewhat the character of the seal coat required. For maintenance within city and town limits, where the horse-drawn traffic is considerable, it has been found that a specially prepared tar, which can be applied cold, gives much better results than the heavier tar materials put on hot.

"Consider the light dust-laying oils and their effect on tar-bound macadam. It is a problem which affects city and town conditions. In country practice, the conditions do not arise where an oil of this type is necessary. On city and town streets, a troublesome dust often collects, which the ordinary seal coat of tar or heavy asphalt does not keep down. In applying a light oil over a tar-bound macadam to keep down this superficial dust, it is essential to comply with certain conditions if the tar-bound macadam is not to be ruined. It is the utmost folly to put a light oil on a tar-bound macadam; if there is the least chance for the oil to penetrate the macadam, the results are sure to be disastrous. The tar-bound macadam will be disintegrated. A light oil has two effects on the tar-bound macadam. It has a chemical effect on the tar which causes its disintegration and makes it lose its binding force. It also has a physical effect on the macadam structure. The oil is a lubricant; and if there is any stone loose enough to move in the tar macadam, the light oil accelerates the movement, and a hole is sure to develop. This dual action of the light oil can be observed in many large cities at the present time, and many streets may be seen which have been built with tar-bound macadam, the life of which has been gradually shortened by the use of light oil. The effects of the light oil can be minimized if the tar-bound macadam is thoroly sealed, either thru an excess of bituminous material in the first place, or by subsequent applications of refined tar. Certain precautions must be taken also in applying the oil. An excess of oil should never be used, and it should be applied to the surface only in sufficient quantity to take up the loose dust which is found there. A very small fraction of a gallon is sufficient. If more than this is applied, the oil gradually sinks into the tar-bound macadam and in the end will rot it."

Mass. Highway Comm. Practice, as described by Dean (16d). "If slight depres-

sions or small holes occur, they are usually due to imperfections in construction and may be repaired by painting with bituminous material and filling with chips or pea stone, or they may be filled with bituminous coated stone, and tamped or rolled. Traffic and climate govern the demands for more extensive maintenance. With moderate traffic, perfection of surface is maintained by spraying the surface about once in 2 years with a lighter grade of tar or asphalt. The process consists in sweeping thoroly the surface, spraying at the rate of about ¼ to ⅜ gal per sq yd, and covering with pea stone. If the surface becomes worn too much for such treatment, it may be restored by lightly scarifying, smoothing by rakes or harrow, adding more stone and rolling it into place, and then following the methods used for new construction. This last method of resurfacing, provided the road foundation was originally properly constructed, may be subsequently repeated as often as necessary, thereby utilizing the permanent base and first course and maintaining a semi-permanent surface good for any except extremely heavy vehicles."

Penn. State Highway Dept. Practice by Biles (19), giving reasons for, and methods of repairing.

"1. A section of road where the surface is composed of spots of excess bituminous material and bare or lean areas where the binder is lacking in quantity, which condition results in a short time in a raveling or breaking up of the road surface. This condition is usually caused by improper distribution or by incorporating the bituminous material when the stone is not thoroly dry. The first case, if taken in time, can be repaired by sealing the dry or lean spots in the surface with a light, heated application of bituminous cement of the binder grade, or the cold bituminous surface treatment materials in quantities ranging from 0.1 to 0.3 gal per sq yd of surface, covered with chips or pea gravel, using between 15 and 20 lb per sq yd. Unless the surface is worn badly, repairs of this character will even up the surface to a true cross-section, giving added life to the pavement.

"2. A rough surface is presented where the stone is loosened or raveled, the binder showing rapid deterioration, generally causing a series of pot-holes. This may be occasioned by improper or overheated bituminous material, unsatisfactory aggregate or faulty sub-drainage. The second condition calls for heroic treatment, if of any great extent, and a complete scarifying and harrowing of the surface becomes necessary. All disintegrated material must be removed and sufficient new stone added to give the required depth before the surface can be repenetrated and sealed as in the original construction. If, however, the affected portions are only occasional and do not represent the greater area, they may be cut out, cleaned thoroly and filled with new stone, making due allowance for compression, then penetrated, etc, in the manner hereinbefore mentioned. If drainage conditions are responsible for the failure they must be corrected before any surface repairs are taken up.

"3. At times there is apparently a lifeless surface in so far as the bitumen is concerned, but upon further examination it is found to contain bituminous binder with considerable life a slight depth below the surface. This condition is due in many cases to an insufficiency of bituminous material. The condition described in the third example may be treated in two ways. The most economical so far as first cost is concerned would be to give the pavement a treatment, in sufficient quantity to fill the surface voids, with a material that will penetrate and enliven the old material, followed by a covering of good, hard stone chips, using about 20 lb per sq yd. The alternative would be to scarify and harrow the whole surface, supplying additional new stone in quantities as the rolling would indicate to be required to give the proper cross-section, and penetrating the surface with a bituminous binder, sealing again as in the original construction. In the latter method, the surface must first be thoroly cleaned, and in scarifying and harrowing, the remaining bituminous material in the road must be distributed as evenly as possible. If the material found in the pavement, however, does not possess life, this method is a hazard.

"4. A pavement may present a wavy and uneven appearance and this is usually due to an excess of bituminous material or is caused by the bituminous material being too soft to withstand the action of traffic. In the wavy, corrugated surface, where there is found to be an excess of bituminous material, it is generally more economical and satisfactory to scarify and reshape the surface, adding new stone in order to take up the excess bitumen, and again sealing the surface. This same method should be followed where waves have been caused by the bituminous material being too soft, only perhaps

more stone would be required in the reconstruction and it would be essential to incorporate a harder bituminous binder than was used in the original construction. Occasional waves in the surface may be taken out in the due course of ordinary repairs by cutting off the high places and resealing, if the conditions are very pronounced or by cutting out the depressions and replacing with new material.

"5. There are surfaces which consist of ridges of material which are the result of irregular or improper pouring; in most cases, careless hand pouring. A surface of this kind suffers quickly from the impact of traffic and the attack of the elements, and early disintegration is the result. A surface full of ridges due to improper pouring, if not too pronounced, may be evened up by painting between the ridges with bituminous cement and covering with stone chips or gravel. This method may be continued from time to time until the surface is entirely evened up. This condition may also be corrected by scarifying the surface with the object of obtaining a more uniform distribution of the old bituminous material and, after rolling to the proper shape, by applying a surface treatment of a cold bituminous material that will enliven the existing material and seal the surface. This treatment is covered with stone chips in the manner prescribed for regular bituminous surface treatment work.

"6. The case of a fairly well-shaped, uniform surface becoming porous. This condition is true of all bituminous highways in time, as it represents the beginning of the deterioration of the bituminous material. In the last case there is a properly constructed bituminous penetration pavement, but the bituminous material is starting to deteriorate. This can be enlivened or revived by cleaning the surface and applying a seal coat of material in quantities depending upon the degree of disintegration. Caution should be exercised to avoid applying an excess amount, which results in a slippery condition and is very objectionable to horse-drawn traffic. Generally 0.1 to 0.2 gal is used and brushed into the surface with hand brooms. The surface is then covered with chips or gravel approximating 20 lb per sq yd. In the use of certain slow drying cold bituminous materials it will be observed that the new material softens up the old bitumen somewhat, giving the appearance at first of an excess application, and, having a hard surface underneath, the road becomes quite slippery, but this condition obtains for only a short period of time. To insure the best results, one-half of the road should be treated at a time in order that the traffic may use the other portion while the bituminous material is setting up. This method has become quite effective and results in increased life to the pavement.

"In the repair of breaks, depressions and local defects, which may occur under any one of the general conditions previously outlined, it is more satisfactory to use hot bituminous binders, and if replacements are necessary they can be made after the fashion of the original construction. This work can be done very efficiently in this manner with little equipment and the average class of labor. There are a number of instances where cold bituminous compounds can and are being used successfully in certain seasons of the year on pavements of this kind, but in cold weather there is usually difficulty with some of this material, owing to its composition. As an example, the emulsified products break down or separate and their adhesiveness is destroyed at low temperatures. Materials that are cut-back with natural solvents can be used later and give very good results. The mixtures can be prepared at some point, not exposed to the weather, but convenient to the work, hauled to the site of the repairs, and deposited. This is an effective method in case of emergency."

N. Y. State Highway Comm. Practice by Sturdevant (16d). "In order to keep the surface of a road in smooth, proper condition, it should be under constant surveillance, and receive constant attention. As the surface becomes worn in places, and holes and ruts develop, they should be repaired at once, for if neglected they rapidly extend in size and depth under the action of each traveling vehicle. On bituminous surfaces, the best results are obtained, if the asphaltic materials are first mixed with stone, gravel, or other suitable ingredients. This mixing can be done at any time, and in sufficient quantities to last for several months, for the weather will not cause the mixed material to deteriorate. The writer has used material which had been mixed during the previous summer and piled by the roadside, and has obtained as good results as with fresh materials. In all patching work, the first requisite is to see that the surface to be repaired is well cleaned before new material is placed; also, in repairing holes and ruts, care must be taken not to use too much asphaltic material, and it is well not to have the new patch flush with the surface, for, under the action of the sun, the

asphalt, whether light or heavy, will come to the surface. Then the patch will become sticky and is likely to be pulled off by heavy slow-going vehicles. To prevent this, more stone and fine material must be used as covering, and if too much was used originally, a hump will develop which is as disagreeable as the original rut or hole. This is not as likely to occur when the material has been mixed before placing, as when the asphalt is placed first and then covered."

Maintenance Cost Data in Portland, Me., by Hunt (39). The data given in the following table pertains to a section of bituminous macadam 2879 ft in length, located on Danforth and Vaughan Sts., between St. John and Bowdoin Sts., constructed in 1908 at a cost of $1.18 per sq yd.

Date	Repairs	Surface Treatment	Total Maintenance	Maintenance per Sq Yd
1908.............	....	......	....	....
1909.............	$ 90.00	......	$ 90.00	$0.0104
1910.............	293.12	306.88	600.00	0.0691

SECTION 16

BITUMINOUS CONCRETE PAVEMENTS

BY

ARTHUR H. BLANCHARD

CONSULTING HIGHWAY ENGINEER, NEW YORK CITY

GENERAL DATA

1. Definitions, Classification and Patent Litigation

Definition Adopted by Spec. Com. Mat. Road Cons., Am. Soc. C. E. (17e). "A bituminous concrete is one composed of broken stone, broken slag, gravel or shell, with or without sand, Portland cement, fine inert material or combinations thereof, and a bituminous cement incorporated together by a mixing method." For an account of the derivation of the terms, bituminous macadam and bituminous concrete, see Sect. 15, Art. 1.

Classification. Bituminous concrete pavements may generally be grouped in three classes. The Spec. Com. Mat. Road Cons., Am. Soc. C. E. (17e), has defined the essential characteristics of the three classes as follows:

"CLASS A. A bituminous concrete pavement having a mineral aggregate composed of one product of a crushing or screening plant.

"CLASS B. A bituminous concrete pavement having a mineral aggregate composed of a certain number of parts by weight or volume of one product of a crushing or screening plant, and a certain number of parts by weight or volume of sand, broken stone screenings or similar material, with or without a filler.

"CLASS C. A bituminous concrete pavement having a predetermined mechanically graded aggregate composed of broken stone, broken slag, gravel or shell, with or without sand, Portland cement, fine inert material or combinations thereof."

Patent Litigation. In connection with the design or selection of a suitable type of bituminous concrete pavement, it is at present (1918) necessary to consider the possibility of an infringement suit being brought by one of the patentees of proprietary pavements. Highway engineers and contractors are primarily interested in the types of bituminous concrete pavements which may be constructed without danger of litigation rather than a voluminous discussion of the probabilities of successfully defending infringement suits.

CLASS A. There is ample evidence at hand that bituminous concrete pavements of Class A may be constructed without danger of litigation proceedings.

CLASS B. The history of litigation cases indicates that the construction of unpatented bituminous concrete pavements of Class B on a large scale will, in all probability, lead to an infringement suit.

CLASS C. With the exception of the class of bituminous concrete pavements having mineral aggregates similar to that covered by the Topeka decree, the extensive use of unpatented bituminous concrete pavements of Class C will usually lead to litigation proceedings.

PRIOR ART. For examples of early literature pertaining to mineral aggregates of the several classes of bituminous concrete pavements, see Art. 2.

PATENTED PAVEMENTS. For descriptions of the mineral aggregates of patented bituminous concrete pavements, see Arts. 6 and 7; for methods of manufacture and construction, see Arts. 14 and 16; and for specifications, see Arts. 15 and 17.

LIABILITY FOR INFRINGEMENT OF PATENTS. If a state, county or municipal department uses a specification for a non-proprietary bituminous concrete pavement of Class B or C, it generally should assume responsibility in case a suit for infringement is brought by a patentee. The practice of requiring the contractor to indemnify the party of the first part should not be followed, except in cases when specifications are used which have been advocated or drawn up by a producing company or a contractor. In the cases of the exceptions noted, the use of the following clause, or one similar thereto, in specifications is justifiable.

"The contractor shall indemnify and save harmless the city against all claims for any infringement of patents or royalty due on same on account of any methods or combinations of materials used on the herein specified work, or for use of any tools, machinery, appliances, devices, or materials used in the construction and completion of the work, and hereby agrees that the Director of Public Service may retain out of the moneys which may be due or become due said contractor under this contract a sum of money sufficient to cover all claims for damages or royalty as above mentioned, and to retain the same until the said claims are paid or satisfactorily adjusted."

N. Y. State Highway Comm. Method of Contracting for Patented Pavements as contained in its specifications for Bitulithic pavement.

"Warren Brothers, owners of the patents used in the construction of Bitulithic Pavement, have filed with the State Commission of Highways a properly executed binding agreement to furnish any contractor desiring to bid for the work all the necessary surface material mixed and ready for use, and bituminous flush coating cement necessary for coating the wearing surface, delivered on wagons of the contractor at the mixing plant, which will be located within 3 miles of the point of use, at a stipulated price per square yard for each contract. Such price for Bitulithic pavement mixture and flush coating composition will include a license to use all the patents required in the construction of the pavement as herein specified. The filing of a bid under these specifications will be construed as an acceptance of the terms of the license agreement filed by the Warren Brothers Co., at the price in said agreement, which is on file with the Secretary of the Commission."

Indemnity Bond for Patented Pavements by Warren (71e). "It is a common and good precautionary custom of municipalities in cases where advance arrangements have not been made for use of the patent to stipulate in the contract and contractor's bond that the contractor and surety shall indemnify the municipality against loss by reason of the infringement of patents involved in the construction. Such bonds should be in a sum sufficient to cover the probable royalty, the amount of which actually depends on the size of contract and in addition thereto at least $50 000, regardlessof the size of the contract, in order to safely cover the cost of defending litigation and the taxable costs in case the final decision is in favor of the patentee if litigation is brought by the patentee against the municipality as an infringing user."

2. Historical Development

The first bituminous concrete pavement was probably constructed about 1840 in Nottingham, England, while in the United States the first construction of this type of pavement was at Knoxville, Tenn., in 1866. From 1870 to 1875 there were about 70 000 sq yd of bituminous concrete pavements laid in Washington, D. C., see (23a). From 1888 to 1893 many yards of coal-tar distillate pavements were laid in Washington because Congress had prohibited the use of sheet-asphalt pavements in the District of Columbia. From 1880 to 1891 several sections of bituminous concrete pavements, using coal tar as the bituminous cement, were laid in Ontario, Can., see (47). Another early bituminous concrete pavement was built in Concord, N. H., and is still in use to-day. During the closing period of the nineteenth century attention was directed in England to the details of construction of bituminous concrete pavements for use on highways outside of built-up districts. In the United States at the opening of the twentieth century, Fred J. Warren urged the use of bituminous concrete as a pavement for streets in competition with sheet-asphalt, wood block, and brick pavements. Based on experimental work begun in 1906, Rhode Island in 1909 was the first state to adopt the bituminous concrete pavement as a standard type of construction for use on state highways. Since 1910 there has been a rapidly growing appreciation of the inherent value of the many different types of bituminous concrete pavements for use on roads and streets. Instances of development in this field of construction will be cited later, in connection with each class of bituminous concrete pavement.

Class A. Pavements of this type have been constructed of one or more courses of bituminous coated metal with and without seal coats of bituminous materials. During the period from 1869 to 1875 many patents were granted by the United States Government covering bituminous concrete of this type.

Patent No. 114 172, granted to F. E. Mathews in 1871, contains the following description of a two-layer bituminous concrete pavement:

" When laid on an ordinary foundation the concrete should be laid in 2 layers or coats and should be from 6 to 8 in thick when finished.

" For the first layer the stone used in making the concrete may be such as would pass thru a screen having a 3-in mesh; about 6 measures of the stone should be mixed with 1 measure of the asphalt mixture and this layer should be about 4 in thick.

" For the second layer or coat the stone should pass thru a screen having a 1½-in mesh, and be mixed with the asphalt mixture in the proportion of about 4 parts of the former to 1 part of the latter, and the second layer should be from 2 to 3 in thick.

" Fine sand or any suitable fine hard substance may be sprinkled over the last coat just before or after rolling, to give the pavement a smooth compact surface."

Many descriptions of old pavements of this type may be found in technical literature. As an illustration may be cited the following specifications used in England in the latter part of the nineteenth century: " The hot stone, when ready for mixing, is screened into material of 3 sizes, 1 to 2 in for the body, ½ to 1 in for the intermediate coat, and ¼ to ½ in for the top dressing. The coarsest material is used in a layer 3 to 4 in thick, the intermediate size forms a coat of about ¾ in, and the top dressing is used in the thinnest layer possible, with a view to filling all interstices. Afterward a dressing of ¼-in and smaller granite screenings is scattered broadcast, and the traffic at once allowed on the road to work this top dressing into the tarred material. Each of the layers is rolled separately with a 10-ton roller."

Class B. This type has been described many times in early technical literature. For example, the following description was published prior to 1885: " The manner of preparing, treating, and laying the asphalt mass is as follows: He took asphalt, 125 parts; petroleum-oil, 25 parts. These substances were melted and thoroly incorporated together, and to this mixture he added, in a heated state, sand or powdered stone, 750 parts, and gravel or broken stone, also heated, 1100 parts. The whole was then thoroly mixed."

U. S. O. P. R. Report on Tar Concrete Pavement Laid in 1875 on Highland Terrace, Washington, D. C.; date of report, Nov. 16, 1909. "This sample was taken from a section of about 2 sq ft cut from the old pavement on Highland Terrace, which was laid in 1875. The section was cut under the supervision of Hubbard and Reeve from midway between the center and gutter on the south side of the street near the middle of the square and a little to the right of the German Embassy when facing it. The general appearance shows it to consist of a dense aggregate of crushed rock and fine sand, thoroly impregnated and bound together with a bituminous cement. The surface consisted of a cushion layer of somewhat finer material than the body of the pavement, approximately ¼-in thick, but the presence of coarse stones was noticeable thruout the surface. This layer was so well incorporated with the body of the pavement that it could not be separated, and the determinations were made upon about 2800 g of recovered mineral matter. Sand was not noticeable in any of the portions above 80-mesh, but was present to a considerable extent in the fine portions.

Bitumen in pavement		6.2%
Mineral aggregate		
Stone retained on 8-mesh sieve		82.8%
Stone retained on 1-in screen	1.6%	
Stone retained on ¾-in screen	6.1%	
Stone retained on ½-in screen	35.7%	
Stone retained on ¼-in screen	41.6%	
Stone passing ¼-in screen	15.0%	
	100.0%	

Stone and sand passing 8-mesh sieve		17.2%
Retained on 10-mesh sieve	16.0%	
Retained on 20-mesh sieve	19.5%	
Retained on 30-mesh sieve	12.0%	
Retained on 40-mesh sieve	16.5%	
Retained on 50-mesh sieve	5.0%	
Retained on 80-mesh sieve	10.5%	
Retained on 100-mesh sieve	3.5%	
Retained on 200-mesh sieve	6.0%	
Passing 200-mesh sieve	11.0%	
	100.0%	
Voids in mineral aggregate		18.5%
Retained on ¼-in screen	70.3%	
Retained on 100-mesh sieve	26.7%	
Retained on 200-mesh sieve	1.0%	
Passing 200-mesh sieve	2.0%	
	100.0%	

Specifications for Washington, D. C. Coal Tar Distillate Pavement, as laid in 1887 (27d).

"The base will be composed of clean, broken stone that will pass thru a 3-in ring, well rammed and rolled with a steam roller to a depth of 4 in, and thoroly coated with hot paving cement composed of No. 4 coal tar distillate in the proportion of about 1 gal to 1 sq yd of pavement.

"The second or binder course will be composed of clean, broken stone, thoroly screened, not exceeding 1¼ in in the largest dimension, and No. 4 coal tar distillate. The stone will be heated by passing thru revolving heaters, and thoroly mixed by machinery with the distillate in the proportion of 1 gal of distillate to 1 cu ft of stone. The binder will be hauled to the work, spread upon the base course at least 2 in thick, and immediately rammed and rolled with hand and heavy steam rollers while in a hot and plastic condition.

"The wearing surface will be 1½ in thick when compacted, made of paving cement, composed of 25% of asphalt and 75% of coal tar distillate, mixed with other materials, as follows: Clean, sharp sand will be mixed with pulverized stone of such dimensions as to pass thru a ¼-in screen, in the proportion of 2 to 1. To 21 cu ft of the above-named mixture will be added 1 peck of dry hydraulic cement, 1 quart of flour of sulphur, and 2 quarts of air-slaked lime. To this mixture will be added 320 lb of paving cement to compose the wearing surface.

"The material will be heated to about 121° C (250° F); the paving cement in kettles, the sand, stone, etc, in revolving heaters. They will be thoroly mixed by approved machinery, and the mixture carried upon the work, where it will be spread upon the binder course 2 in thick with hot iron rakes and other suitable appliances and immediately compacted with tamping irons, hand and steam rollers, while in a hot and plastic state. The surface will be finished with a dusting of dry hydraulic cement rolled in. The pavement so constructed must be a solid mass 6 in thick, and will be thoroly rolled and cross-rolled until it has become hard and solid."

Pavements of Class B have been used in several municipalities since 1900. For example, in Washington, D. C., bituminous concrete pavements have been constructed in accordance with the following specifications covering the mineral aggregate: "The paving material shall be composed of crushed trap rock screenings, concrete sand, and mineral dust in the following proportions: Trap rock screenings, 2 parts; concrete sand, 1 part, and mineral dust, at least 5% of the above aggregate; mixed with asphaltic cement." The trap rock screenings referred to above varied in size from 1 in to screenings and were devoid of dust. See Art. 6.

Class C. Specifications for pavements of this type call for predetermined mechanically graded aggregates. From a historical standpoint reference

is made to the description of the Excelsior Pavement, as it includes the characteristic features of this class, namely, that "several sizes are mixed to form a close mass without cavities." This description is made up of pertinent abstracts from a book entitled "The Excelsior Pavement," the advertisement of which is dated 1871.

"The Excelsior Pavement consists of a broken stone, or McAdam base, covered with a concrete surface, which, being close, smooth, and coherent, presents but little resistance to travel, and permits no movement among the stones that compose it; therefore, scarcely any dust or mud is formed; its superiority over others is manifest.

"The resisting material may be sand for the surface, gravel or broken stone mixed with sand for the middle, and larger stone for the bottom, or bed; broken stone alone is preferred, sizes being chosen which best form a compact structure, smooth on top, and strong thruout. Small fragments are not generally required. Several sizes are mixed to form a close mass without cavities, the coarser stone being put beneath. This material should be carefully selected for its strength and resistance, and contain no dirt or other foreign matter.

"The sand, gravel, or broken stone of different degrees of coarseness, as laid at or below the surface, should be sharp, clean and hard; the cement should be uniform, fluid and adherent during mixture; and the compound should condense and harden rapidly under manipulation, being composed of the greatest amount of rock, and the least of cement, which will form a mass most resembling stone itself."

In 1907 the author discovered a printed specification in the Library of the Am. Soc. C. E. entitled "Specifications for the Excelsior Pavement." The following excerpt covers the description of the mineral aggregate:

"Broken stones are preferred for the whole pavement, and shall alone be used for the covering. The greatest dimension of stones for the base, except as hereinafter noted, shall be between 3 in and ¼ in, and for the covering between 2 in and 1/20 of an in; the sizes shall be mixed in proportion, varying with the size to form a close mass, which, when dry and compact, can absorb not more than 20% of water."

Bitulithic Bituminous Concrete Pavement. Since the beginning of the twentieth century a large amount of a proprietary pavement known as "Bitulithic" has been laid in the United States. As described by Fred J. Warren, the wearing surface, which usually has a thickness of about 2 in after compression, is constructed as follows: "The mineral or stone part is dried and heated in a modern drier and is then separated by screening with a rotary screen into its sizes, varying from fine dust, which is less than 1/200 of an in in diameter, to the largest size used. The several sizes of stone are then mixed in predetermined proportions, so as to reduce the voids to about 10%, in a modern twin plug steam power mixer, and the hot bituminous cement is added in the mixer in sufficient quantity to not only coat every particle and fill all of the remaining voids, but with enough surplus to furnish to the mixture after compression a rubbery and slightly flexible condition." See Art. 7.

Topeka Bituminous Concrete Pavement. Since 1911 many thousands of yards of pavement of Class C have been laid under the so-called Topeka specifications. A decree was signed in 1910 by certain city officials and representatives of the Warren Brothers Company covering the use of the Topeka mineral aggregate. The following quotation is from the decree to which reference has been made: "It appearing to the court that

of the mineral matter used in the pavements actually constructed in the cities of Topeka and Emporia, Kan., no particles of stone were used that would not pass a screen with openings ½ in in diameter, and that less than 10% of the stone or coarse sand used would be retained upon a screen with openings ¼ in in diameter, and the remaining mineral matter used being finer than ¼ in; and it further appearing that pavements constructed by the use of mineral particles as above described do not infringe the claims of complainant's patent No. 727 505, sued upon in this case; . . . And it further appearing that the pavements as actually constructed in the cities of Topeka and Emporia, Kan., do not infringe the claims of complainant's patent No. 727 505, sued upon in this case, and that any pavements hereafter constructed in substantial compliance with the following formula, to wit:

"Bitumen, from 7% to 11%
Mineral aggregate, passing 200-mesh screen, from 5% to 11%
Mineral aggregate, passing 40-mesh screen, from 18% to 30%
Mineral aggregate, passing 10-mesh screen, from 25% to 55%
Mineral aggregate, passing 4-mesh screen, from 8% to 22%
Mineral aggregate, passing 2-mesh screen, less than 10%

sieves to be used in the order named, would not infringe the claims of said patent." See Art. 7.

Seal Coats on Bituminous Concrete Pavements. The value of the use of seal coats of bituminous cements was appreciated by some of the pioneers in this field of highway improvement. In 1876, Abbot (1) presented the following pertinent discussion on this detail of construction:

"It is the practice of most of the concrete pavement men to finish the surface with a top dressing of dry sand, rolled into the surface; or of hydraulic cement, swept in with a broom. I became early satisfied that some better plan of finishing was needed. The most compact concretes are more or less porous on the surface; and tho these pores are filled with the sand or cement used for top dressing, neither of these materials being waterproof, in wet weather the water penetrates the pavement, street dirt mingles with the water, and a disintegrating process begins, which soon results in breaks and unevenness of surface. In winter, particularly, the moisture, having penetrated the pavement, freezes and thaws, and decay is hastened. It is just as essential that a concrete pavement should be waterproof as that a roof should not leak. My experiments in this direction resulted in what is known as the Abbot Grit Surface, which was patented June 17, 1873. This improvement consists in spreading a hot liquid composition over the surface of the pavement after it is rolled, into which is placed clean, dry grit or sand. This sand is immediately rolled into the surface while the composition is warm, and a tough coating is thereby formed, which not only prevents the pavement from being slippery, but effectually closes every pore in the surface, and makes it impossible for moisture to penetrate."

3. Characteristics

Advantages. All of the advantages resulting from the construction of bituminous surfaces on macadam and gravel roads (see Sect. 14) and of bituminous macadam pavements (see Sect. 15), except low first cost and rapidity of construction, may be cited verbatim with reference to bituminous concrete pavements. Bituminous concrete pavements are usually more stable and durable than other bituminous pavements constructed with

broken stone, gravel, or broken slag. The methods employed in the construction of bituminous concrete pavements permit the most suitable kinds and grades of bituminous cements to be used. The proper use of mixing methods insures homogeneous wearing courses having all particles of the aggregates uniformly coated with bituminous cement. As the aggregate is usually heated at a mixing plant, delays of construction, due to wet weather, are not as prolonged as in the case of bituminous macadam pavements. By the use of modern mixing plants, it is practicable to lay certain types of bituminous concrete pavements of Class A as economically as it is possible ordinarily to build bituminous macadam pavements.

Disadvantages. Slipperiness with seal coats of some bituminous materials may occur and thus prove a disadvantage. Skilled labor is required, and, for some types, expensive plant equipment is essential.

4. Drainage, Subgrades, Foundations and Edgings

Drainage. As bituminous concrete pavements are impervious, the utmost care must be taken to secure, by thoro underdrainage, dry, natural foundations. If the road-bed is not properly drained, water may be held in contact with the undersurface of the wearing course and cause disintegration; in other cases displacement of the wearing course is liable to take place due to freezing and thawing of the road-bed, settlement of embankments, the force of water from springs, and the general weakening of the natural foundation. The use of cement-concrete foundation or broken stone foundations does not prevent underground water from reaching the bituminous wearing course as both types are pervious to water. For a detailed discussion of underdrainage, see Sect. 8, Arts. 6 and 7.

Subgrades. For methods of constructing subgrades, see Sect. 8, Art. 3.

Foundations. For all classes of bituminous concrete pavements, foundations of gravel, broken stone or slag, old macadam, bituminous macadam and concrete, old brick and stone-block pavements, and cement-concrete have been used. The foundation should be strong enough to carry the traffic to which the pavement is to be subjected. Many failures have occurred due to laying bituminous concrete pavements on weak foundations. Satisfactory results have been obtained under medium traffic with thoroly filled and compacted broken stone, and bituminous concrete foundations. Cement-concrete foundations have been used successfully under the heaviest traffic for which the several classes of bituminous concrete are suitable, especially in cases where the road-beds have been well drained. For a discussion of the relative advantages and the methods of construction of the different kinds of foundations see Sect. 8, Arts. 10 to 20 inc., and Sect. 17, Art. 3.

Penn. State Highway Dept. Practice Relative to Foundations by Uhler (66). "Bituminous concrete and sheet-asphalt pavements should be laid on a concrete base, instead of on the old existing macadam foundation, which, heretofore, has been the generally accepted practice for country roads. In view of the increased amount and change in character of traffic, even tho slightly more expensive, it is advisable to provide for either a 4 or 5-in concrete base on top of the broken stone or telford base, due to the tendency of macadam to shift or to consolidate further under traffic and possible subgrade trouble, all of which tend to bring about a wavy or uneven condition of the surface. In resurfacing old water-bound macadam roads, where the base consists of either telford or macadam, the broken stone surface should be removed to a depth sufficient to conform to the required cross-section and grade. Where the telford surface is exposed, the irregularities are broken off with a napping hammer and the depressions filled in, and upon this prepared surface is placed a 4-in concrete base,

mixed in the proportion of 1:3:6, laid so as to secure a very rough but regular surface to form a bond between the concrete base and the bituminous top. In conjunction with the concrete base a concrete header curb should be constructed extending 6 in beyond the fixed edges of the bituminous pavement and to the finished grade. After the concrete base has developed a hard set, and from 1 to 2 days prior to the placing of the bituminous wearing surface, the base should be cleaned thorgly of loose and foreign material, by sweeping, and then covered with an asphaltic cut-back mixture consisting of equal parts, by volume, of asphaltic cement, 55 to 65 penetration, and commercial naphtha, 52 to 55 gravity, the mixture being applied by a pressure distributor at the rate of 1/8 gal per sq yd. The object of this paint coat is to secure a better bond between the concrete base and the bituminous top."

Specifications for Subgrade, Sub-Drainage and Foundations Adopted in 1916 by the Am. Soc. Mun. Imp., as a part of the specifications for Topeka and Bitulithic pavements.

"**Subgrade.** The contractor will be required to do all of the grading necessary to bring the surface to the proper subgrade as determined by the lines and grades given by the engineer. If the material at subgrade is of an unstable character and unfit for foundation, the contractor shall make such additional excavation as may be determined by the engineer and refill with approved material. After all necessary grading has been done to bring this surface to subgrade, the street shall be thoroly rolled with an approved road roller weighing not less than 10 tons. If settlement occurs the depressions shall be filled and then re-rolled until the surface is solid, uniform and parallel with the grade and cross-section of the finished pavement. All filling shall be free from animal or vegetable matter and of a character approved by the engineer. In case of spongy or yielding subgrade some other means besides ordinary rolling and sprinkling must be employed to obtain satisfactory compaction of the subgrade. In case of loose, sandy soils, a small amount of cinders, gravel or fine crushed stone spread over the surface will often put it in a condition to be compacted under the roller. In the case of clay soils that puddle up and wave or creep under continued rolling, it is best to roll as dry as possible and to be sparing in the use of water when rolling the first layer of macadam. Cinders, gravel or stone screenings will often help in rolling such subgrades.

"**Sub-Drainage.** When the soil is of such a character that it retains an excessive amount of moisture, such as clay, subject to swelling or heaving under the action of frost, or sands similar to quicksand that do not afford a ready natural drainage, subdrains should be provided. These may be of two general kinds: (1) Tile drains of porous material or of vitrified tile laid with open joints; (2) trenches filled with broken stone, gravel, cinders or other similar material. In some cases it may be sufficient to construct a sub-drain on each side of the roadway at or near the lines of the gutters, but when the soil is of a very wet nature it may be advisable to lay additional lines of drains which may be in or near the middle of the roadway. This system of drains may be varied by diagonal lines of drains running from near the crown of the roadway to the gutters. In all cases the drains should have connections with the existing sewers, catch-basins or inlets.

"**New Macadam Foundation.** If the pavement is to be laid on a new macadam foundation or base, the latter shall be built as follows: The total thickness of the macadam base will vary according to character of soil, drainage, kind of stone available, etc. In general, the macadam base should be constructed of broken stone which is sound, hard and durable under traffic. The broken stone should be separated into different sizes by screening, the smaller sizes with the dust being used to fill and bond together the larger sizes. The thickness of the base should be regulated by experience in constructing ordinary water-bound macadam roads in similar situations, the total thickness of pavement, including wearing surface, being made the same or a little less than well constructed macadam.

"After the subgrade has been carefully prepared, spread a layer of clean stone passing a 3 to 3½-in revolving screen and held on a 2-in screen to a depth sufficient when thoroly rolled to form about ⅔ of the total thickness of the base. The thickness of this layer should be regulated by laying on the subgrade at proper intervals, cubical blocks of wood of the proper dimensions to give the desired thickness. Over this layer of stone, spread, with shovels, stone screenings in sufficient quantity to fill the

voids between the larger stone. The screenings should be spread gradually and thoroly rolled with a road roller weighing at least 10 tons during the process of spreading the screenings. As the screenings are worked into the coarse stone under the roller, more should be added here and there where voids appear. At first the rolling should be done dry until the stone appears to be well filled, then the surface should be well sprinkled and again rolled, the rolling and sprinkling continued until the layer of stone is thoroly compacted and no more screenings can be forced in. Just enough screenings shall be used to fill and bond the stone, leaving no surplus screenings on th top.

"The above method may be varied by using the crusher run of stone without addition of any other filler where the small sizes are not in excess. Also a filler other than stone screenings, such as bank gravel or sand, may be used in some cases where experience with materials available shows better results can be obtained. Under some conditions the character of soil and stone available may be such as not to require the use of any filler with the stone of the first course. The specifications given, however, represent the best average practice where stone with bonding value, such as limestone or trap rock, can be obtained.

"When the first layer of macadam is completed as specified, spread a second layer of clean stone passing a 2 or 2½-in screen and held on a 1-in screen to a depth sufficient when thoroly rolled to form the remaining ⅓ of the total thickness of the base. Over this layer of stone spread evenly with shovels stone screenings and roll with the application of water by sprinkling. The sprinkling and rolling shall be continued until the stone is well bonded and until no more compression can be observed under the roller. Just enough filler should be used to accomplish this purpose and not enough to form a layer or film over the surface of the stone. It is better not to fill the stone quite flush, leaving the coarse particles of stone slightly projecting, so as to have a coarse, grainy base upon which to put the wearing surface.

"As an alternate method of construction, the macadam may be well filled with screenings, watered and rolled until flushed up smooth. Over the surface of the macadam base thus constructed shall be spread a third layer of clean stone of a size to pass a 2-in ring and be retained on a 1-in ring. This layer of stone should average 1 in after rolling or practically only one stone deep and is for the purpose of forming a binder or key between the base and wearing surface and thus preventing lateral displacement of the surface. After being spread evenly it shall be lightly rolled only enough to partially imbed the stone and set them firmly in place without crushing or forcing sufficient fine material up from below to fill the surface voids entirely. The final rolling should be done while the macadam base is still moist and comparatively soft.

"The thickness of the pavement, including base and wearing surface, should vary according to local conditions and should be fixed by the engineer in charge when all the varying conditions of soil, drainage, traffic and materials of construction are understood. In general, a thickness of macadam base of 8 in with a wearing surface of 2 in will be enough for any except the most adverse conditions, and a base of 4 to 5 in with a wearing surface of from 1½ to 2 in will meet the most favorable conditions of firm, unyielding soils and light traffic.

"Old Macadam Foundation. If the pavement is to be laid on an old macadam foundation, the surface shall be thoroly swept and cleaned of all fine material that may be caked upon the surface of the stone or lying loose as dust, thereby exposing the clean, coarse stone for the reception of the bituminous concrete. If the old macadam does not present the desired coarse, grainy surface, or is not at proper and satisfactory grade after cleaning, it shall be spiked up and redressed to the desired crown and grade, the coarse stone being brought to the top by harrowing or otherwise, or new stone added where needed. It shall then be watered and rolled until thoroly compacted. If the result is not the required coarse, grainy surface, a layer of clean stone shall be spread and lightly rolled as described above in the paragraph relating to new macadam foundation.

"Cement-Concrete Foundation. When a Portland cement-concrete foundation is used, it should be laid according to the standard specifications adopted for concrete foundation. The surface, however, should be roughened to form a key for the wearing surface. This may be done by using coarse stone of fairly uniform size and laying

the concrete fairly wet, or by brooming, washing with a hose before hard set, tamping with grooved rammers, or by spreading a light layer of coarse, clean stone over the fresh concrete and lightly tamping."

Protection of Edges of Bituminous Concrete Pavements. The edges of bituminous concrete roadways on streets are protected, as they are usually built between sidewalk curbs or between paved gutters of brick, stone block, or cement-concrete. In the case of bituminous concrete pavements outside of urban districts, however, the edges generally are not supported by gutters or sidewalk curbs. Many roadways are built with earth shoulders adjoining the bituminous concrete. Under such conditions, especially when the width of roadway is not adequate to accommodate the traffic, the inevitable result is the breaking off of the edges of the bituminous concrete. Instances have occurred on 16-ft roadways, subjected to heavy commercial traffic, where, during 1 year, the edges have been broken off for a width of 4 to 10 in.

Abnormal wear of edges may be prevented by several methods: (1) Increasing the width of the roadway of bituminous concrete so that the probable traffic will not be forced near the edges. (2) Construction of thoroly compacted and puddled shoulders of gravel or broken stone with or without thin bituminous surfaces. (3) Use of edgings of wood, steel shapes, stone block, cobblestones, or cement-concrete. (4) Construction of the English or French raised verge or shoulder which has a depth of 3 to 5 in.

In the United States, cement-concrete edgings or curbs are most generally used. They should be built of 1:1½:3 or 1:2:4 cement-concrete, and have a width of not less than 6 in. However, their use should not be considered an argument for the construction of roadways having widths inadequate to carry the traffic to which they probably will be subjected. If the roadways are not wide enough to accommodate the traffic, usually bad ruts will be worn in the bituminous concrete adjacent to the cement-concrete edgings, the formation of the ruts being followed by the breaking off of both the cement-concrete edgings and the bituminous concrete.

The method to be adopted in any particular case will depend upon the amount and character of the probable traffic, the available width for the roadway and other parts of the highway, the comparative economical value of the different methods of protecting the edges based on local conditions, and the amount of money immediately available for the improvement.

Conclusions. Spec. Com. Mat. Road Cons., Am. Soc. C. E. (17e). "Where bituminous pavements are laid, the edges need protection, and a sudden transition from the pavement to any soft shoulder material should be avoided by means of extra width, or of cement-concrete or other edges, or such reinforcement of the shoulder material as may be necessary."

Economy of Using Cement-Concrete Curbs (50b). "The good reputation of asphalt wearing surfaces is based largely upon the performance of such surfaces on city streets, where curbs are almost invariably provided. In proportion to the traffic carried, such side support is just as necessary on roads as for pavements. A very good example of the truth of this statement was noted recently (1917) during the inspection of a Long Island Topeka specification road, now 5 years old, and in good condition except along the edges, where the asphalt top was almost continuously broken down along the shoulder of the road. The maintenance of something more than a mile of this road for the 5-year period would have amounted to practically nothing but for the repairs necessary at the edges of the road, all of which would have been avoided if a concrete curb or header had been provided in the first instance."

U. S. O. P. R. 1916 Specifications for Cement-Concrete Edgings. "Concrete curbs shall be built on the base as shown on the plans. The concrete shall be composed of the following materials, by volume: 1 part of cement, 1½ parts of sand, 3 parts of gravel or crushed stone, and water. The materials shall be thoroly mixed in a machine

mixer of the batch type or by hand. If the mixing is done by hand, it shall be done upon a water-tight platform with raised edges, in such manner as to insure thoro mixing of the materials and to meet the approval of the engineer. The concrete for the curb shall be placed upon the base before the concrete of either the curb or the base has taken its initial set, and care shall be taken, such as roughening the concrete of the base and tamping the concrete of the curb, to insure that the curb will be firmly bonded to the base. The concrete shall be well tamped and spaded along the forms, so that when they are removed there will be no open and porous places on the sides of the curb. The top surface of the curb shall be floated or troweled to a smooth finish. The forms for the curb shall be smooth, clean, free from warp, and of sufficient strength to resist springing out of shape. They shall be well staked and braced, and the top edges shall be at the same height and set true to line. To protect the curb from drying out too rapidly it shall, within 12 hr after it is placed, be covered with gunny cloth, which shall be kept wet for 5 days."

MATERIALS

5. Mineral Aggregates for Class A Pavements

Class A Bituminous concrete aggregates consist of one product of a crushing or screening plant. The non-bituminous materials used as aggregates for Class A bituminous concrete pavements are broken stone, broken slag, gravel, and oyster shells. Broken stone and broken slag are the principal materials used, due primarily to the desirable stability being more readily obtained than with gravel, while the use of oyster shells has resulted from consideration of low first cost in some sea-coast districts.

Broken Stone. Trap rock, limestone, granite, and syenite have been used extensively, and, to a limited extent, sandstone, gneiss, and field stone have been employed. Altho trap rock generally makes the best aggregate for pavements subjected to heavy commercial traffic, and gneiss and field stone make unsatisfactory aggregates, the latter due to its non-uniform qualities, it is poor practice to specify acceptable rock merely by geological names (see Sect. 11, Art. 5). The rock should meet definite physical requirements, which will depend upon the traffic to which the pavement will be subjected, local economic factors, and, in some cases, details of the method of construction. It is desirable that the broken stone be hard, to resist wear caused primarily by the grinding action of iron-tired vehicles, and tough, to resist impact forces such as blows of horses' hoofs and the hammering action of heavy iron-tired wheels as they pass over obstructions on the surface of the roadway. Altho the Dorry test is used as a direct measure of hardness, the Deval test gives the only reliable indication of the resistance to abrasion of broken stone. The limiting values to be given to resistance to abrasion and toughness requires consideration of all local conditions. If, for example, the roadway is to be subjected primarily to rubber-tired motor vehicle traffic, a rock having a toughness of not less than 6 and an abrasion loss of not more than 6%, would give good results. If used on a roadway carrying a daily commercial traffic of 300 iron-tired horse-drawn and motor trucks, a rock having a toughness of not less than 13 and a loss of abrasion of not over 3.5% should be used.

Shape, Character of Surface and Cleanliness. See Sect. 15, Art. 5.

Products or Sizes. Due to the variability in the sizes of particles of broken stone contained in products obtained under the common forms of specifications, it is usually necessary to adopt more rigid requirements covering the composition of the product rather than its method of manufacture. For a discussion of variation in products of broken stone, see Sect. 11, Art. 6. For specifications and formulas covering the composi-

tion of broken stone products, see Art. 8, AM. SOC. MUN. IMP. CLASS A SPECIFICATIONS, and Sect. 11, Art. 7, AM. SOC. C. E. AND AM. SOC. TEST. MAT. FORM OF SPECIFICATION. If broken stone is obtained from stationary commercial plants, the methods to which reference is made always should be used. In case of portable plants, altho the specification form recommended is the most satisfactory for general use, local conditions may be such that the following type of specification will prove more adaptable, especially in cases where contractors or local quarrymen are not accustomed to furnishing broken stone to meet requirements covering the several sizes of broken stone in a product.

"For the wearing course 1½-in stone shall be used, and stone chips shall be used for the seal coat. The screening plant or plants for supplying broken stone shall be equipped with revolving screens, 9 to 12 ft long and from 30 to 36 in in diameter, having perforations as follows: First section, ½-in holes; second section, 1½-in holes; third section, 3-in holes. The sections of screen shall be of acceptable lengths. A dust jacket having ¼-in circular perforations or composed of a 4-mesh sieve shall surround the first section; it shall be 6 to 9 in shorter than the ½-in screen and about 6 in greater in diameter. Broken stone dust passing the ½-in screen and retained on the dust jacket is designated in these specifications as stone chips. Broken stone passing over the ½-in screen and thru the 1½-in screen is designated as 1½-in stone."

In using specifications of the above type, a clause should be inserted which would require that the crushing and screening plant be operated in accordance with the direction of the engineer in so far as such operation effects the composition of the several products of broken stone. The specifications quoted were used with successful results by the Board of Water Supply of the City of New York in connection with the construction of 32 miles of Class A bituminous concrete pavements. Seven crushing and screening plants were efficiently operated under the direction of the Board's engineers in order to obtain the products desired for the foundation course, the wearing course of bituminous concrete and the stone chips for the seal coat.

ANALYSES OF AGGREGATES FOR ONE-LAYER PAVEMENT. The following analyses of aggregates from three different contracts are given as illustrations of satisfactory products for use in the construction of one-layer pavements of Class A when broken stone or broken slag is used for the aggregate. By reference to Art. 8, it will be seen that all of the products meet the requirements of the Am. Soc. Mun. Imp. specifications.

	A	B	C
Passing ⅛-in screen	1.2%	2.7%	1.0%
Passing ¼-in screen	4.2%	5.6%	2.5%
Passing ½-in screen	34.7%	45.0%	30.8%
Passing ¾-in screen	40.6%	35.1%	34.2%
Passing 1-in screen	17.3%	10.1%	23.4%
Passing 1¼-in screen	2.0%	1.5%	8.1%
	100.0%	100.0%	100.0%

AGGREGATES FOR TWO OR THREE-LAYER PAVEMENTS. Many combinations of products have been successfully used in the construction of two and

three-layer bituminous concrete Class A pavements in England. For examples of English practice, see Art. 12. Altho pavements of this type have been constructed in the United States and Canada, its use since 1900 has been confined to a few localities. The AMIESITE pavement, see Art. 15, altho laid in layers, is not referred to here, as it comes under Class B pavements.

Broken Slag has not been extensively used in the United States. The excellent bituminous slag concrete pavements which have been constructed in England since 1900 indicate that from slag, possessing the essential physical and chemical properties, an aggregate, equal in quality to one of broken stone, can be manufactured. To make a satisfactory aggregate, slag must be clean, rough-surfaced, dense and tough, and possess no glossy surfaces. The Ohio State Highway Dept. requirements are as follows: "The broken slag shall be clean, sound, durable, and of uniform quality and shall contain not less than 32% of silica and not more than 25% of calcium oxide and not more than 1.5% of sulphur. Slag shall show in the abrasion test a loss of not more than 10%, a hardness of not less than 16, and a toughness of not less than 5. Slag aggregates shall weigh not less than 75 lb per cu ft." A slag, meeting the Ohio specifications, should only be used on light traffic roads. The slag used in England is so dense that it resembles trap rock, and has a high toughness and a low loss on abrasion.

SIZES OF SLAG. In England, slag is used for one, two, and three-layer bituminous concrete pavements of Class A. Typical English commercial products of slag are as follows:

2¼-in gauge, pieces varying from 2¼-in to 1½-in;
1½-in gauge, pieces varying from 1½-in to ½-in;
⅝-in gauge, pieces varying from ⅝-in to ⅛-in.

If used in three layers, the 2¼-in product would be used for the bottom layer, the 1½-in for the middle, and the ⅝-in for the top layer. For details of use, see Art. 12.

Gravel. Due to the variability in the composition of bank gravel, the probability that the particles of gravel will be coated with more or less clay, and the characteristic rounded surfaces of gravel, the use of gravel for Class A bituminous concrete has been very limited. If crushed, clean gravel is used, the results may be satisfactory, but it should not be expected that the resulting pavement will be as durable as one having an aggregate of well interlocked broken stone or broken slag. For specifications covering essential properties of gravel for bituminous concrete aggregates, see Art. 8.

Conclusions, Spec. Com. Mat. Road Cons., Am. Soc. C. E. (17e). "Broken stone, because of the satisfactory bond secured, should be used wherever possible, altho bituminous concretes constructed with gravel have proved satisfactory for light traffic where great care has been taken in the selection of the gravel and in the construction of the pavement.

"Broken stone should be clean, rough-surfaced, sharp-angled, of compact texture, and uniform grain. If the pavement is to be subjected to medium or heavy traffic, the broken stone used for the construction of the wearing course should show a loss or abrasion of not more than 3.5%, and its toughness should not be less than 13.

"Especial care is required in drafting the specifications covering the broken stone or gravel to be used. An excess of large or small sizes of stone or gravel should be avoided. Practice has demonstrated that a mineral aggregate which will comply with the following mechanical analysis, using laboratory screens having circular openings, will produce satisfactory results: All the material shall pass 1¼-in screen; not more than 10% nor less than 1% shall be retained on a 1-in screen; not more than 10% nor less than 3% shall pass a ¼-in screen."

Essential Physical Properties of Gravel, Slag and Broken Stone by Smith (60b). "GRAVEL should be clean grained, hard, and free from adhering clayey particles. It is lacking in stability owing to the roundness of its particles and is usually considerably improved by passing it thru a crusher. Gravel with a rough pitted surface is to be preferred and gravel containing a large percentage of flinty particles is to be avoided. It is unsuitable for the construction of pavements carrying heavy traffic and inferior in all respects to crushed stone.

"SLAG. Hard, dense, basic slag is to be preferred. Should be stable when exposed to weather and not show any tendency to slack or disintegrate. Only suitable for light traffic and should preferably be coated with a very fluid bitumen.

"BROKEN STONE. Should be freshly crushed, preferably in cubical shaped particles. Size and hardness required depends upon the traffic which the pavement is to carry. Dense hard limestone will carry medium and light traffic satisfactorily. When the traffic, tho light in volume, is composed of heavy iron-tired units, a dense hard trap is required. Trap is now commonly used for asphalt block manufacture, altho in the past a large number of asphalt blocks made from limestone gave excellent service under light traffic. Granite is not usually satisfactory as it is too coarse and uneven in texture and much of it is friable and it is liable to shatter in crushing."

Character of Surface of Gravel, Slag and Broken Stone by Smith (60b). "Broadly speaking, a rough, pitted and somewhat absorbent surface is the best. Smooth glossy surfaces do not readily retain a thick coating of bitumen and require a relatively high heat to insure properly coating them. At a high heat the bitumen becomes very liquid and readily runs off of them, which results in a coating of undesirable thinness. Even when the temperature at which they are coated is no higher than that employed with rough surfaces, their smoothness permits the bitumen to drain off more readily. This is particularly the case with flint particles; and sand containing them, when coated with bitumen and examined under a glass, invariably show the minimum thickness of coating on the flint particles sharply contrasting with the surrounding rougher surfaced quartz particles which have retained a coating of normal thickness. As compared with a non-absorbent surface, an absorbent one *per se* is to be desired. Unfortunately most particles which have absorbent surfaces are lacking in resistance to wear and therefore, notwithstanding their superiority from the standpoint of coating them with bitumen, are not suitable for heavy traffic, more especially of the iron-tired variety. Where the bituminous cement used is lacking in cementing value an absorbent surface is especially necessary.

"The outer surface of the particles must be firmly adherent to and form a permanent part of the particles themselves and must show no tendency to scale off when heated. Certain sands upon heating appear to form loosely adherent scales upon the surface of their particles which are not removed by attrition in the mixer but which under the stress of traffic and atmospheric changes in temperature become loose and detach themselves, carrying the coating of bitumen with them. Pavements laid with this type of sand have been known to disintegrate from this cause alone within a few weeks from the time they were laid. Gravel, freshly broken slag, and stone are ordinarily free from this defect. Slag which is glassy does not coat as well with bitumen as do the more basic slags."

Maximum Size Stone in Bituminous Concrete by Warren (71b). "Our practice on this point has always been to have the maximum sized stone in the aggregate 40 to 50% of the thickness of pavement surface except that on crushed stone or bituminous base a larger sized stone may be used, because a considerable portion of the larger particles of aggregate will crowd into the spaces between the coarse, generally 3-in, stone in the foundation and in reality make the total wearing surface 50% greater than the 2 in specified."

6. Mineral Aggregates for Class B Pavements

Class B bituminous concrete aggregates consist of a certain number of parts by weight or volume of one product of a crushing or screening plant, and a certain number of parts by weight or volume of sand, broken stone screenings, or similar materials, with or without a filler.

Broken Stone, Broken Slag and Gravel. For discussion of essential physical properties, see Art. 5,

Sand and Filler. For discussion of different kinds of sands and filler and the essential physical properties thereof, see Sect. 17, Arts. 4 and 5.

Filler for Aggregates by Mullen (49c). "The inorganic dust or filler is a factor of prime importance. The material most commonly used is limestone dust pulverized in a grinding mill to such fineness that at least 75% will pass a standard 200-mesh testing sieve. When the material is less fine, more must be added to secure a given result. Stone dust and Portland cement are the most widely used filler materials, the former being the most common because the lower in cost, but the latter being preferred by some on the ground that it is thought to make a superior mixture. When Portland cement is employed, the difference in specific gravity between that material and the remainder of the mineral aggregate should be taken into consideration, as the mixtures are usually figured by weight instead of by volume, tho the latter would seem a more logical method if it could be used with reasonable convenience. Other filler materials are pulverized clay, marl, shale, silica, etc. Many materials have been tried and found satisfactory, but a few have produced disastrous results. The 200-mesh sieve is not a sufficient test for an inorganic dust filler, except for routine work on a known material. The particles of dust that are of the most value are those that would pass a 500-mesh sieve, were one of such fineness of practical value for laboratory testing."

Composition of Aggregates. The conclusions of the Spec. Com. Mat. Road Cons., Am. Soc. C. E. (17e) are as follows: "Specifications for pavements of this class have generally stipulated that so many parts of broken stone or gravel and so many parts of sand or other fine material are to be mixed with a certain quantity of bituminous cement. By the use of this specification, and with unusual supervision, it is practicable to secure a fairly well-graded aggregate, but in most cases the mixture will be found to contain an excess of broken stone, with insufficient fine material to fill the voids therein, and in other cases it will contain an excess of sand in which the broken stone is held as isolated particles."

A typical specification covering the mineral aggregate of a Class B pavement is as follows: "The stone to be used shall be good, durable granite, trap rock, or limestone, and shall be the run of the crusher passing a 1½-in ring and shall not contain more than 5% of dust. Clean, coarse sand shall be used as a filler in the proportions found necessary and approved by the engineer in charge. The bituminous concrete shall have the following composition: Crushed stone, 53 to 62%; sand, 30 to 37%; asphalt cement, 8 to 10%." In this form of specification, a rough attempt is made to fill the voids in one product of a crushing and screening plant by a mortar of sand and asphalt cement. Altho a satisfactory mix may result, there is no assurance that a well-proportioned aggregate will be obtained. As explained in Sect. 11, Art. 6, the composition of broken stone products vary to a marked degree when furnished under the above type of specification. Further, the requirement that a definite percentage of coarse sand be used is no guarantee that the sand will be composed of the proper sizes to combine with the product of broken stone which the contractor or producer will furnish. To secure the best mix obtainable for Class B pavements, the broken stone product should be specified as recommended in Art. 5, and definite specifications should be used covering the sand and filler similar to those found in the specifications for Topeka aggregates, see Arts. 8 and 17.

Conclusions on Composition of Mortar by White (73b). "Following are the analyses of the mortar constituent, that is, 10-mesh material or less, of several samples of asphaltic concrete which have been under traffic for long enough periods of time to demonstrate their good or bad qualities. The first four proved to be very good, and the latter two indifferent in quality.

	No. 1	No. 2	No. 3	No. 4	No. 5	No. 6
Bitumen	18.8%	18.9%	16.1%	21.0%	18.9%	16.3%
Passing 200-mesh sieve	10.8%	11.6%	11.7%	10.9%	4.3%	3.5%
Passing 80-mesh sieve	10.6%	11.5%	7.0%	26.2%	5.9%	5.7%
Passing 40-mesh sieve	36.8%	35.3%	22.7%	19.3%	50.3%	54.1%
Passing 10-mesh sieve	23.0%	22.7%	42.5%	22.6%	20.6%	20.4%
	100.0%	100.0%	100.0%	100.0%	100.0%	100.0%

"As far as the coarse aggregate is concerned, that is, all material coarser than 10-mesh, there were considerable variations in the different samples, but the total quantity was approximately the same, and the variations seemed to have nothing to do with the success or failure of the sample. Samples 1 to 4 were successful, and they were rich in dust and reasonably well proportioned in other sizes up to 10-mesh. Samples 5 and 6 were practically failures, and they are seen to be lean in dust with an excess of 40-mesh material not well filled by the smaller sizes."

Washington, D. C., Aggregates, as described by Brooke (23b). "The proportions of coarse and fine aggregate for the bituminous concrete were fixed after a number of sieve tests of local sand and trap rock at about 2 parts by volume of stone to 1 of sand, to which is added about 5% of dust to supply the deficiency in fine material of the stone aggregate. The ingredients consist of crushed trap rock devoid of dust and varying in size from 1 in to screenings, sand, mineral dust and asphaltic cement. A hard-grained, moderately sharp sand is used. Upon sifting at least 25% must be caught on a 20-mesh sieve and 5% pass an 80-mesh. A deficiency in fine sand may be corrected with mineral dust, which consists of fine Portland cement or limestone dust, at least 85% of which passes a 100-mesh sieve and the whole of which passes a 30-mesh.

"An apparent defect in this specification is the lack of any requirement as to grading of the stone. It is evident that the composition of the mixture might vary within wide limits. However, from Table I, showing the average of the tests of the mixtures actually laid in five working seasons, it will be seen that the aggregate runs fairly uniform. The sand is tested before use for compliance with the specification for that material but no attempt is made at selection, or separation or grading of any sort of the run-of-crusher stone. The material below the 8-mesh is fairly uniform, due no doubt to the sand entering into this part of the mixture. The increase in material passing 100-mesh from 1910 to 1911 is due to a change in specifications increasing the amount of mineral dust. In the 1910 mixture only about 1% of dust was added, whereas not less than 5% has been used since."

Table I.—Average Grading of Bituminous Concrete Mixtures, Washington, D. C., 1910–1914

	1910	1911	1912	1913	1914
Passing 100-mesh sieve	3.2%	7.8%	6.3%	8.0%	8.8%
Passing 80-mesh sieve	1.6%	1.7%	1.2%	1.0%	0.8%
Passing 60-mesh sieve	6.2%	3.6%	3.5%	3.2%	3.2%
Passing 40-mesh sieve	10.7%	7.0%	7.0%	6.1%	5.8%
Passing 20-mesh sieve	10.7%	6.6%	8.0%	13.0%	12.3%
Passing 10-mesh sieve	1.3%	3.0%	4.9%	10.2%	8.0%
Passing 8-mesh sieve	0.3%	1.0%	1.3%	3.8%	2.8%
Passing 4-mesh sieve	2.6%	9.6%	9.5%	17.0%	14.5%
Passing ½-in screen	19.2%	21.2%	26.3%	19.2%	25.2%
Passing ¾-in screen	30.0%	18.0%	18.7%	13.7%	17.6%
Passing 1-in screen	13.0%	20.2%	12.8%	5.0%	0.0%
Passing 1¼-in screen	1.0%	0.0%	0.3%	0.0%	0.0%
Specific gravity of stone	2.85	....	2.93	2.97	2.86
Specific gravity of sand	2.69	....	2.70	2.70	2.68
Percentage of voids in aggregate	26.40	....	21.98	20.76	21.39
Percentage bitumen soluble in CS_2	7.10	6.80	6.90	7.35	6.80

7. Mineral Aggregates for Class C Pavements

Class C bituminous concrete aggregates consist of predetermined mechanically graded broken stone, broken slag, gravel or shell, with or without sand, Portland cement, fine inert material, or combinations thereof.

Broken Stone, Broken Slag and Gravel. For discussion of essential physical properties, see Art. 5.

Sand and Filler. For discussion of different kinds of sands and fillers and the essential physical properties thereof, see Art. 6 and Sect. 17, Arts. 4 and 5.

Composition of Topeka Aggregates. The conclusions of the Spec. Com. Mat. Road Cons., Am. Soc. C. E. (17e) are as follows:

"If the Topeka pavement specification embodies the grading, as contained in the decree of 1910, namely:

Bitumen, from 7 to 11%;
Passing 200-mesh sieve, from 5 to 11%
Passing 40-mesh sieve, from 18 to 30%
Passing 10-mesh sieve, from 25 to 35%
Passing 4-mesh sieve, from 8 to 22%
Passing 2-mesh sieve, less than 10%

special provisions should be made in the specifications covering the broken stone and sand to be used, in order to secure satisfactory grading."

The above recommendations relative to the necessity of more definitely specifying the composition of Topeka aggregates are based on the wide range of combinations of broken stone and sand, or similar materials, which may be used under the 1910 decree formula and the fact that many failures have resulted from the use of poorly graded mixtures. Three forms of specifications covering the Topeka mineral aggregates have been used successfully.

1. The grading of the broken stone and sand have each been covered by specific requirements and the mixed aggregate required to comply with 1910 formula. As an example, the following specifications are quoted, in part. The broken stone shall pass a ½-in screen and shall be so graded that when combined in a bituminous mixture containing not less than 30% of the sand hereafter specified shall produce a bituminous mixture complying with the 1910 decree formula. All particles of the sand shall pass a 10-mesh sieve, and shall contain at least 15% of material retained on a 40-mesh sieve and at least 20% of material that will pass an 80-mesh sieve except as hereinafter provided for. If the sand does not contain the required amount of fine material, mineral dust may be added to make up the deficiency.

2. The broken stone and sand have been covered by general requirements and the mixed aggregate by more detailed requirements than embodied in the 1910 decree formula. This type of specification was adopted by the Am. Soc. Mun. Imp., see Art. 8.

3. Each of the items, broken stone, sand, and mixed aggregate, has been covered by specific requirements, as in the case of U. S. O. P .R. specifications, see Art. 8.

Topeka Pavements as Laid on Riverside Drive, New York, and in Rochester, N. Y. by Richardson (57b). "A fine asphaltic concrete surface was laid on Riverside Drive in New York in the autumn of 1913, data in regard to which are shown in Table II, in which column A gives the average composition of the surface mixture as laid on the street, and column B that of the finer portion, excluding the particles of 4 and 2-mesh size and the bitumen, 4%, which is regarded as sufficient to cover them.

Table II.—Proportions in Asphaltic Concrete Surface on Riverside Drive, New York

Composition			A	B
Asphalt cement	110 lb	Bitumen	8.9%	11.1%
Portland cement dust	110 lb	200-mesh	11.9%	16.5%
Sand	312 lb	80-mesh	14.5%	20.1%
Stone screenings	564 lb	40-mesh	18.6%	25.9%
		10-mesh	18.9%	26.4%
	1096 lb	4-mesh	19.1%	......
		2-mesh	8.1%	......
			100.0%	100.0%

"These figures demonstrate what the character of the finer portion of the mixture may be regarded as a sheet-asphalt surface, to which the stone or grit size has been added. It is seen that this is very satisfactory from that point of view, containing a proper percentage of bitumen and filler, altho the material passing a 10, 20 and 30-mesh sieve is high. It is to be noted that the mixture is much improved by the fact that the filler was Portland cement. It seems reasonable to believe that this surface may be regarded as the highest type of one that is stone-filled or known as fine asphaltic concrete. The results developed by service tests will be of interest.

"In this connection it is worthy of observation that a mixture of this type is being laid in Rochester, N. Y., at the present time (1914), and has been so used for 12 years. The Rochester mixture closely resembles that on Riverside Drive, containing Portland cement as a filler, and has proved itself by service tests, since the date given, to be entirely satisfactory. This mixture has the composition shown in Table III.

Table III.—Mixture Used at Rochester, N. Y.

Composition	Original Mixture	Finer Portion
Bitumen	8.9%	11.1%
200-mesh	12.3%	17.1%
100 and 80-mesh	10.8%	15.0%
50 and 40-mesh	24.2%	33.7%
30, 20 and 10-mesh	16.3%	22.7%
4-mesh	21.5%	......
2-mesh	5.4%	......
	99.4%	99.6%"

Composition of Patented Bituminous Concrete Pavement Aggregates. The conclusions of the Spec. Com. Mat. Road Cons., Am. Soc. C. E. (17e) are as follows: "In cases where patented bituminous concrete pavements of Class C are used, the same fundamental principles observed under Class A pavements should be followed, especially in the case of covering in detail the composition and grading of the mineral aggregate." The following specification, as used by a state highway department to cover the mineral aggregate of a patented pavement, illustrates the indefinite requirements condemned by the committee of the Am. Soc. C. E. "The several grades and sizes of mineral aggregate shall be accurately measured in proportions previously determined by laboratory tests to give the best results, that is, the most dense mixture of mineral aggregate and one having inherent stability." The use of the above form of general descriptive specification allows the contractor to furnish an aggregate which may vary in composition between wide limits. Definite specifications which will control the character

and uniformity of the aggregate of any patented bituminous concrete pavement can be prepared to cover any local conditions. For examples of definite requirements covering aggregates of patented pavements, see the Bithulithic specifications of Los Angeles, Cal., Art. 8; the Bitulithic specifications of Portland, Ore., Art. 16; and the Penn. State Highway Dept. Warrenite specifications, Art. 8.

Differentiation of Bitulithic and Warrenite bituminous concrete mixtures. The following statement was prepared by George C. Warren, President of the Warren Brothers Co., for the information of the engineers enrolled in the Graduate Course in Highway Engineering at Columbia University.

"Bitulithic and Warrenite mixtures are both made under the provisions of the Warren patents, which the courts have held 'cover the product no matter how produced.' Bitulithic is designed to meet the conditions generally prevailing on city streets, and Warrenite is to meet such conditions as may arise on country roads so as to meet the physical and economic conditions and public demands as to cost.

"Generally speaking, Bitulithic is mixed by a plant which is too cumbersome to meet country road conditions, which provides for combining the materials proportioned by separation of sizes of the aggregate, after heating, and then recombining by weight. Warrenite is, generally speaking, mixed by a plant so portable that it may be set up either alongside the railroad, along the side of the road being constructed, or in the quarry or gravel bank from which the bulk of the aggregate is being procured, as may be most economical in any particular case. This plant is constructed on the principle of proportioning the several separate sizes by careful measurement by bulk before heating and retaining the batch so measured as a separate entity thru the process of heating and delivery into the mixer in which the bituminous cement is added.

"Generally speaking, crushed stone predominates in the fine aggregate of Bitulithic, while sand predominates in the fine aggregate of Warrenite; also, fine crushed stone and sand respectively are correspondingly used for the seal coat aggregate. In the selection of quality of material, whether gravel or crushed stone, for the coarse aggregate a greater latitude is permitted in the case of Warrenite to practically meet the conditions of less opportunity for selections which are liable to prevail in localities a considerable distance from railroad centers. This latitude is allowed, because, while the traffic conditions on country road thorofares are in point of weight and concentration of traffic rapidly becoming fully as severe as on most city streets, there is the important difference that on country roads generally the traffic is more exclusively of the motor vehicle rubber tire type and consequently less exaction in physical properties of the quality of the stone forming the basis of the aggregate is necessary. Also, unfortunately, many city streets are abused by constant excessive sprinkling or daily scoured by pressure flushing machines, a practice which is more or less injurious to any road surface, while the country roads are seldom, if ever, wet except by rainfall; therefore, in cases where the very best quality of stone is unavailable, it would be safe to use stone of slightly lower quality in Warrenite on a country road, altho the same quality stone might not be safe for use in Bitulithic on a city street."

8. Specifications for Mineral Aggregates

Class A. Am. Soc. Mun. Imp. 1917 Specifications for Broken Stone Aggregate are as follows:

"**Quality.** All broken stone shall be clean, rough-surfaced and sharp-angled, of compact texture and uniform grain.

"**Tests.** The broken stone shall be subjected to abrasion and toughness tests conducted by the engineer in accordance with methods adopted by the Am. Soc. Test. Mat., Aug. 15, 1908. The broken stone used for the construction of the wearing course shall show a loss on abrasion of not more than 3.5% or a French coefficient of wear of not less than 11.5, and its toughness shall not be less 13.0.

"**Broken Stone for Mineral Aggregate.** Broken stone for the mineral aggregate of the wearing course shall consist of one product of a stone crushing and screening plant. It shall conform to the following mechanical analysis, using laboratory screens having circular openings: All of the broken stone shall pass a 1¼-in screen; not

more than 10% nor less than 1% shall be retained upon a 1-in screen; not more than 10% nor less than 3% shall pass a ¼-in screen."

Class A. U. S. O. P. R. 1918 Specifications for Broken Stone Aggregate are as follows:

"**General.** The broken stone shall consist of angular fragments of rock, excluding schist, shale and slate, free from thin or elongated pieces, soft or disintegrated stone, dirt or other objectionable matter, occurring either free or as a coating on the stone.

"**Physical Properties.** The stone shall meet the following requirements: French coefficient of wear, not less than 8; toughness, not less than 8.

"**Chips.** That portion of the product of the crusher which, when tested by means of laboratory screens, will meet the following requirements:

Passing ½-in screen, not less than	95%
Retained on ¼-in screen, not less than	85%

"**Aggregate.** That portion of the product of the crusher, which, when tested by means of laboratory screens, will meet the following requirements:

Passing 1-in screen, not less than	95%
Total passing ¾-in screen	25 to 75%
Retained on ½-in screen, not less than	85%

"**Methods of Testing.** Tests of the physical properties of the rock and of the sizes of broken stone products shall be made in accordance with the following methods:

1. French Coefficient of Wear: Bul. U. S. Dept. Agr., 347, p. 5.
2. Toughness: Bul. U. S. Dept. Agr., 347, p. 15.
3. Size: Bul. U. S. Dept. Agr., 555, p. 32.

"**Notes:** This specification is intended to cover stone to be used in the construction of a bituminous concrete wearing course and seal coat. The broken stone aggregate for the concrete proper is a single size of crusher product with no exact grading limitations. It may, therefore, produce what is commonly known as an open mix, and will carry from 5 to 7% bitumen. Such mixture may be placed on a well compacted broken stone or gravel foundation or a cement-concrete foundation so as to produce, after rolling, a wearing course 2 in in depth. A seal coat of bituminous material should then be applied and covered with chips in sufficient quantity to take up all excess of bitumen."

Class B. U. S. O. P. R. 1918 Specifications for Mineral Aggregate of Broken Stone, Sand and Filler are as follows:

"**Broken Stone.** GENERAL. The broken stone shall consist of angular fragments of rock, excluding schist, shale, and slate, free from thin or elongated pieces, soft or disintegrated stone, dirt or other objectionable matter, occurring either free or as a coating on the stone.

"PHYSICAL PROPERTIES. The stone shall meet the following requirements: French coefficient of wear, not less than 8; toughness, not less than 8.

"CHIPS. That portion of the product of the crusher which, when tested by means of laboratory screens, will meet the following requirements:

Passing ½-in screen, not less than	95%
Retained on ¼-in screen, not less than	85%

"COARSE AGGREGATE. That portion of the crusher which, when tested by means of laboratory screens, will meet the following requirements:

Passing 1-in screen, not less than	95%
Total passing ¾-in screen	25 to 75%
Retained on ½-in screen, not less than	85%

"**Sand.** GENERAL. The sand for fine aggregate shall be composed of sound, durable stone particles, free from a coating of clay or loam.

"GRADING. When tested by means of laboratory screens and sieves, the sand shall meet the following requirements:

Passing ¼-in screen	100%
Total passing 40-mesh sieve	30 to 70%
Retained on 200-mesh, not less than	90%

"**Mineral Filler.** GENERAL. The mineral filler shall consist of limestone dust, dolomite dust, Portland cement or natural cement. It shall be free from foreign or other objectionable material.

"FINENESS. When tested by means of laboratory sieves, the mineral filler shall meet the following requirements:

Passing 30-mesh sieve 100%
Total passing 200-mesh sieve, not less than 65%

"**Methods of Testing.** Tests of the physical properties of the rock and of the size or mechanical analysis of broken stone, sand and mineral filler shall be made in accordance with the following methods:

1. French Coefficient of Wear: Bul. U. S. Dept. Agr., 347, p. 5.
2. Toughness: Bul. U. S. Dept. Agr., 347, p. 15.
3. Size of Broken Stone: Bul. U. S. Dept. Agr., 555, p. 32.
4. Mechanical Analysis of Sand and Mineral Filler: Bul. U. S. Dept. Agr., 555, p. 33.

"**Notes:** This specification is intended to cover the mineral constituents of a roughly proportioned bituminous concrete consisting of from 45 to 60% broken stone coarse aggregate, from 30 to 45% sand or fine aggregate, from 3 to 5% mineral filler, and from 5 to 8% bitumen. It should preferably be placed upon a cement-concrete foundation so as to produce, after rolling, a wearing course 2 in in depth. A seal coat of bituminous material should then be applied and covered with chips in sufficient quantity to take up all excess of bitumen."

Class B. Cleveland, 1917 Specifications for an Aggregate of Broken Stone, Sand and Dust.

"**Description.** The mineral aggregate shall consist of a mixture of broken Bessemer limestone, or other limestone equally as good, trap rock or granite, and sand, to which shall be added a small quantity of stone dust or Portland cement.

"**Sizes.** The stone shall vary in size from that passing a 1¼-in screen to as small as that held on a ¼-in screen. The dust or fine screenings shall be removed from the stone.

"The sand shall be hard-grained, moderately sharp, free from loam or other foreign material and varying in size from that passing a ¼-in screen to dust passing a 200-mesh sieve. There shall not be over 5% passing the 200-mesh sieve and there shall not be over 30% held on the 10-mesh sieve.

"The dust which shall be added to the mixtures shall be either a Portland cement or ground limestone.

"The Proportions of the various ingredients composing the bituminous concrete shall be approximately 3 parts of stone to 2 parts of sand, to which shall be added bituminous cement sufficient so that from 7 to 10% by weight of the mixture shall be bitumen soluble in carbon disulphide. The stone dust or Portland cement added to the mixture shall be in such quantities that a screening of the whole aggregate shall not show more than 6% by weight passing a 200-mesh sieve."

Class C. Form of Specifications for Topeka Coarse and Fine Aggregates adopted at the first conference of State Highway Testing Engineers and Chemists held at the U. S. O. P. R. in Feb., 1917 (67c):

"**Coarse Aggregate.** GENERAL. The broken stone for coarse aggregate shall consist of angular fragments of (insert types allowable), free from thin or elongated pieces, soft or disintegrated stone, dirt, or other objectionable matter, occurring either free or as a coating on the stone.

"PHYSICAL PROPERTIES. The stone shall meet the following requirements:

Percent of wear .... not more than ....
or French coefficient .... not less than ....
*Hardness .... not less than ....
*Toughness .... not less than ....
*Absorption .... not more than ....

"GRADING. The broken stone for coarse aggregate, when tested by means of laboratory screens, shall meet the following requirements:

Passing (the largest size selected) .. in screen 100%
Passing (the largest size selected) .. in screen and retained on (the second largest size selected) .. in screen .... % to .... %
†Passing, etc, ...

* Tests recommended by the conference, which it may be desirable to omit in some instances.

† The number and sizes of screens may be continued as desired by the engineer. The last requirement should be:
Passing 10-mesh sieve .... not more than ...... %.

"METHOD OF SAMPLING. Stone shall be sampled for quality and grading in accordance with the method described on page ...., paragraphs ...., of these specifications.

"METHODS OF TESTING. Tests of the physical properties and grading of the stone shall be made in accordance with the methods described on pages .... of these specifications, tests Nos. ....

"Fine Aggregate. GENERAL. The fine aggregate shall be composed of sound, durable particles of stone or sand. The particles shall be free from a coating of clay or loam.

"GRADING. The broken stone or sand for fine aggregate, when tested by means of laboratory sieves, shall meet the following requirements:

Passing 10-mesh sieve............................	not less than...%
Passing 10-mesh and retained on 40-mesh sieve.......	% to.......%
Passing 40-mesh and retained on 80-mesh sieve.......	% to.......%
Passing 80-mesh and retained on 200-mesh sieve.......	% to.......%
Passing 200-mesh sieve............................	% to.......%."

Class C. Am. Soc. Mun. Imp. Specifications for Topeka Mineral Aggregate, as adopted in 1916, are as follows:

"General. The mineral aggregate shall consist of a mixture of broken stone and sand, to which shall be added as required, stone dust or Portland cement.

"Broken Stone. Any sound, durable stone, either trap rock, limestone or granite, usually considered suitable for macadam, may be used. It should be broken as nearly cubical as practicable. It should not show distinct planes of cleavage or crystalline faces and should not readily crush or split under the roller when being rolled in the pavement. Between two kinds of stone, choice should generally be made of the one showing the greater toughness rather than hardness. A certain percentage of absorption, such as is shown by the better grades of limestone, is a desirable quality, as the bonding strength of the cement is somewhat improved thereby.

"The Sand shall be hard-grained, moderately sharp, free from loam or other foreign material and varying in size from that passing a ¼-in screen to dust passing a 200-mesh sieve, and there should not be over 10% held on the 10-mesh sieve, nor over 5% passing the 200-mesh sieve.

"Dust in the form of finely ground stone or Portland cement may be added to the mixture, but in such quantities that the screenings of the total ingredients entering into the mix shall in no case show over 10% by weight passing a 200-mesh sieve.

"The Proportions of the various ingredients composing the bituminous concrete shall be as follows:

Bitumen..	7 to 9%
Passing 200-mesh sieve............................	7 to 10%
Passing 80-mesh sieve, but retained on a 200.............	10 to 20%
Passing 40-mesh sieve, but retained on an 80.............	10 to 25%
Passing 20-mesh sieve, but retained on a 40.............	10 to 25%
Passing 8-mesh sieve, but retained on a 20.............	10 to 20%
Passing 4-mesh sieve, but retained on an 8.............	15 to 20%
Passing 2-mesh sieve, but retained on a 4.............	5 to 10%

"The minimum amount of bitumen allowed shall be used only in mixtures containing the minimum total passing the 80-mesh. The percentage of bitumen must be increased above the minimum as the total passing the 80-mesh increases.

"The item designated as dust includes, in addition to the stone dust or Portland cement that may be added, such fine sand passing a 200-mesh sieve as may be found self-contained in the sand to be used, and such 200-mesh mineral as may be self-contained in the refined asphalt."

Class C. U. S. O. P. R. 1918 Specifications for Modified Topeka Aggregate are as follows:

"Broken Stone. GENERAL. The broken stone shall consist of angular fragments of rock, excluding schist, shale and slate, free from thin or elongated pieces, soft or disintegrated stone, dirt, or other objectionable matter, occurring either free or as a coating on the stone.

"SIZE. It shall be that product of the crusher which, when tested by means of laboratory screens, will meet the following requirements:

Passing ½-in screen, not less than	95%
Retained on ¼-in screen, not less than	20%

"**Sand.** GENERAL. The sand shall be composed of sound, durable stone particles, free from a coating of clay or loam.

"SIZE. When tested by means of laboratory screens and sieves, the sand shall meet the following requirements:

Passing ¼-in screen	100%
Retained on 200-mesh sieve, not less than	90%

"**Mineral Filler.** GENERAL. The mineral filler shall consist of limestone dust, dolomite dust, Portland cement, or natural cement. It shall be free from foreign or other objectionable material.

"FINENESS. When tested by means of laboratory sieves, the mineral filler shall meet the following requirements:

Passing 30-mesh sieve	100%
Total passing 200-mesh sieve, not less than	65%

"**Total Mineral Aggregate.** GENERAL. The total mineral aggregate shall consist of a uniform mixture of the broken stone, sand and mineral filler, the required grading of each being such as to produce, when properly proportioned, a mixture conforming to the following limitations for grading. The exact proportion of each constituent producing a total mineral aggregate within these limitations shall be as directed by the engineer.

"GRADING. When tested by means of laboratory screens and sieves, the total mineral aggregate shall meet the following requirements:

Passing ½-in screen and retained on ¼-in screen	5 to 10%
Passing ¼-in screen and retained on 10-mesh sieve	11 to 25%
Passing 10-mesh sieve and retained on 40-mesh sieve	7 to 25%
Passing 40-mesh sieve and retained on 80-mesh sieve	11 to 36%
Passing 80-mesh sieve and retained on 200-mesh sieve	10 to 25%
Passing 200-mesh sieve	5 to 11%

"**Methods of Testing.** Tests of the size or mechanical analysis of broken stone, sand, and mineral filler shall be made in accordance with the following methods:

1. Size of Broken Stone: Bul. U. S. Dept. Agr., 555, p. 32.
2. Mechanical Analysis of Sand and Mineral Filler: Bul. U. S. Dept. Agr., 555, p. 33.
3. Grading of Total Mineral Aggregate: Bul. U. S. Dept. Agr., 555, pp. 32 and 33.

"**Notes:** This specification is intended to cover the mineral constituents and grading for bituminous concrete of a modified Topeka, or stone-filled sheet-asphalt type. It is so drawn that from 10 to 50% of broken stone will be required and the mixture of very fine broken stone and sand will possess a satisfactory sheet-asphalt grading. Such an aggregate will carry from 7 to 11% of bitumen. It should preferably be placed upon a cement-concrete foundation to a compacted depth of 2 in. No seal coat will ordinarily be required."

Class C. Penn. State Highway Dept. 1917 Specifications for Warrenite Mineral Aggregate.

"The Warrenite surface paving mixture shall consist of approved crushed stone, with or without the addition of sand, graded in the following proportions so as to give the wearing surface a useful degree of density, rigidity, inherent stability and freedom from voids:

Material passing a 1¼-in screen and retained on a 2-mesh sieve	40 to 60%
Material passing a 2-mesh sieve and retained on a 4-mesh sieve	10 to 20%
Material passing a 4-mesh sieve and retained on a 10-mesh sieve	10 to 5%
Material passing a 10-mesh sieve and retained on a 30-mesh sieve	10 to 5%
Material passing a 80-mesh sieve, at least 25% of which will pass a 200-mesh sieve	10 to 5%

"The balance to pass a 30-mesh sieve and be retained on a 60-mesh sieve."

Class C. Los Angeles, Cal., 1917 Specifications for Bitulithic Mineral Aggregate.

"Upon the foundation, previously prepared and thoroly swept free from all rubbish, shall be laid the Bitulithic wearing surface composed of a mixture of broken stone, sand, stone dust and Bitulithic Waterproof Cement, in sufficient quantities to make the mixture conform to the following proportions by weight:

Passing 1½-in screen and retained on a 1-in screen......	**10 to 15%**
Passing 1-in screen and retained on a ½-in screen.....	**25 to 35%**
Passing ½-in screen and retained on a ¼-in screen.....	**12 to 20%**
Passing ¼-in screen and retained on a 10-mesh sieve....	**8 to 12%**
Passing a 10-mesh and retained on a 200-mesh sieve......	**24 to 32%**
Passing a 200-mesh sieve............................	**4 to 7%**
Bitulithic Waterproof Cement........................	**7 to 9.5%**

"From 60% to 80% of the aggregate passing a 10-mesh sieve shall pass a 40-mesh sieve and from 15 to 30% of the sand shall pass an 80-mesh sieve."

For additional specifications for mineral aggregates of bituminous concretes of Classes A, B, and C, see Arts. 13, 15 and 17, respectively.

9. Bituminous Cements

The bituminous cements which have been used successfully in the construction of bituminous concrete pavements include asphalt, water-gas tar and coal tar cements, and cements which are combinations of refined tars, and combinations of refined tars and asphalts.

Bituminous Cements for Class A Aggregates. All of the types of bituminous cements enumerated have been used in the construction of Class A pavements. If unheated aggregate is used, very good results have been obtained with all the different types except asphalt cements. With unheated road metal it is not usually practicable to coat the unheated aggregate with the most efficacious grades of asphalt cement. For light traffic highways, however, successful results have been secured by using a cut-back asphalt cement. Except for the so-called cold patching methods used in maintenance work, heated aggregates should always be used if machine mixing methods are employed, thus permitting the use of the most suitable types and grades of bituminous cements.

Bituminous Cements for Seal Coats of Class A Pavements. Conclusions, Spec. Com. Mat. Road Cons., Am. Soc. C. E. (17e). "Experience has demonstrated that the most efficacious bituminous concrete pavements of Class A are constructed by using suitable asphalt cements or refined tars in the mix, and asphalt cements for seal coats. Satisfactory results will be secured when tar cements are used for seal coats, but the surface must be retreated more frequently than when asphalt cements are used."

Results of Rhode Island and New York City Service Tests with Seal Coats. In 1909 a series of service test sections was constructed on a Rhode Island state road subjected to mixed traffic of about 100 horse-drawn vehicles and from 250 to 300 motor-cars per day, many of the motor-vehicles being of the large touring-car type and traveling at high speeds. These experimental sections were constructed to determine the most economical and satisfactory bituminous material to be used for the cement in the mix and for the seal coat for bituminous concrete pavements subjected to the above class of traffic. Asphalt cement, refined water-gas tar, refined coal tar and combinations of refined coal tar and asphalt were employed in the construction of the sections. In each section, the same material was used for the binder and the seal coat, except in one section in which coal tar was used in the mix and asphalt cement for the seal coat. The results secured from these experiments, based upon an examination in 1912, indicate that for this class of combination traffic or for horse-drawn vehicle or iron-

tired traffic exclusively, the seal coat generally should consist of an asphalt cement, as being more economical and efficacious than refined tar, or a combination of refined tar and asphalt. I. W. Patterson, Chief Engineer, State Board of Public Roads of Rhode Island, states (53a), as a result of investigations made in 1914, that " it was shown conclusively that a seal coat of asphalt is much more permanent than a seal coat of refined tar, altho the refined tars gave excellent results as far as their binding of the mineral aggregate was concerned.

The same conclusion has been reached as the results of service test sections constructed in the Borough of Queens, New York City, in 1911. In this instance a bituminous concrete, with tar used as the cement and seal coat, required retreatment with a seal coat in 1912, while the section constructed with tar cement in the mix and an asphalt cement as the seal coat did not require a new seal coat when inspected in 1916. See Art. 23 for record of maintenance and traffic data pertaining to the Borough of Queens sections.

Bituminous Cements for Classes B and C Pavements. Asphalt and tar cements have been used in the construction of most of the types of Class B and Class C pavements since 1910. Variation in practice is well illustrated by the use of both tars and asphalt cements in the construction of Topeka pavements. Tar concrete pavements, similar in composition to the Topeka pavement were constructed in Washington, D. C., Pittsburgh, Pa. and the New England states between 1870 and 1895. After the 1910 decree was announced, practically all Topeka pavements were constructed with asphalt cements due, without doubt, to its similarity, in part, to the sheet-asphalt pavement. Since 1913, tar cements have been used in the construction of Topeka pavements in several cities of the Middle West and also in cities of New England, and in 1916 the Am. Soc. Mun. Imp. incorporated alternate specifications for asphalt and tar cements in its Topeka pavement specifications.

Bitumen Content in Wearing Course Mixtures. In specifications and records of work the bitumen content of bituminous concretes is expressed in one of two ways: First, as the number of gallons per square yard or cubic yard of mineral aggregate; and, secondly, as a certain percentage by weight of the wearing course mixture. The latter method is more accurate and definite, and is generally employed. It is apparent that the amount of bituminous cement used by the second method materially depends upon the specific gravities of both the mineral aggregate and the bituminous cement, see Sect. 12, Art. 44.

Forms of Reports for Bituminous Cements. See Sect. 15, Art. 7.

Sources, Manufacture, Physical and Chemical Properties, Tests, Transportation, Storage, and Inspection of Bituminous Materials. See Sect. 12.

Toughness of Bituminous Aggregates. Reeve and Lewis (56) have drawn the following conclusions from concurrent field and laboratory investigations; using standard toughness cylinders composed of 8 to 50-mesh rock mineral aggregates and bituminous cements, which were tested in a Page impact machine with a 500-g hammer. "(1) The toughness of bituminous aggregates in which a given bituminous material is used will not be the same for every type of rock. (2) Tests of laboratory specimens can be directly correlated with results in service. (3) The difference in behavior of the various rock types can not be directly attributed to any of the routine physical test values of the rock, but appears to be due largely to differences in the surface character of the rock particles. (4) While relatively soft or fluid bitumens may yield satisfactory results in bituminous concrete with some types of rock, their use with other types will lead to failure of the road surface. (5) The impact or toughness test of bituminous aggregates offers possibilities as a means of determining in advance the relative behavior in service of bituminous concretes."

10. Specifications for Bituminous Cements

Am. Soc. Mun. Imp. 1917 Specifications for Bituminous Cements to be Used with a Mineral Aggregate Consisting of One Product of a Stone Crushing and Screening Plant:

"General. The asphalt cement or refined tar used in the construction of the wearing course of the bituminous concrete pavement shall conform with either one of the specifications covering the chemical and physical properties of bituminous cements designated Asphalt Cement A, B, C, D and E, and Refined Tar F and G. If asphalt cement is used in the bituminous concrete wearing course, the same asphalt cement shall be used for the seal coat. If refined tar is used in the bituminous concrete wearing course, an asphalt cement shall be used in the seal coat and shall conform with either one of the specifications covering the physical and chemical properties of asphalt cements, designated Asphalt Cement H, K and L.

"Previous Service. The contractor will be required to show, to the satisfaction of the engineer, that the company manufacturing the asphalt cement or refined tar he proposes to use under a given specification has, for a period of at least 2 years, manufactured asphalt cement or refined tar in a thoroly equipped plant, and that asphalt cement or refined tar manufactured of bituminous material obtained from a similar source to that which he proposes to use, shall have been in continuous and successful use for a period of at least 2 years in bituminous pavements constructed by the mixing method previous to the date of the letting in which his proposal was submitted.

"Asphalt Cement A optional with asphalt cements B, C, D, E, and refined tars F and G.

1. The asphalt cement shall be homogeneous, free from water and shall not foam when heated to 177° C (350° F).

2. It shall show a flash point of not less than 205° C (400° F).

3. Its specific gravity at a temperature of 25° C (77° F) shall be not less than 0.970 nor more than 1.000.

4. When tested with a standard No. 2 needle by means of a Dow penetrometer, or other penetrometer giving the same results as the Dow machine, it shall show penetrations within the following limits for the conditions stated, the penetrations being expressed in hundredths of a centimeter: 100 g load, 5 sec, at 25° C (77° F), from 75 to 90; 200 g load, 1 min, at 4° C (39° F), not less than 35; 50 g load, 5 sec, at 46° C (115° F), not more than 250.

5. Its melting point as determined by the cube method shall be not less than 55° C (131° F).

6. When 50 g of the material is maintained at a uniform temperature of 163° C (325° F) for 5 hr in an open cylindrical tin dish, 5½ cm (about 2¼ in) in diameter, with vertical sides measuring approximately 3½ cm (about 1⅓ in) in depth, the loss in weight shall not exceed 1% of the original weight of the sample.

The penetration of the residue, when tested as described in clause (4) with a standard No. 2 needle under a load of 100 g, for 5 sec at 25° C (77° F) shall be not less than one-half the penetration of the original material tested under the same conditions.

7. Its bitumen as determined by its solubility in chemically pure carbon disulphide at room temperature shall not be less than 99.5%.

8. It shall be soluble in chemically pure carbon tetrachloride at room temperature to the extent of not less than 99.5% of its bitumen as determined by clause (7).

9. It shall be soluble in 86° to 88° B paraffin naphtha, at least 85% distilling between 40° and 55° C (104° and 131° F), to the extent of not less than 70% nor more than 80% of its bitumen as determined by clause (7).

10. It shall yield not less than 8% nor more than 12% of fixed carbon.

"Asphalt Cement B optional with asphalt cements A, C, D, E, and refined tars F and G.

1. The asphalt cement shall be homogeneous, free from water and shall not foam when heated to 177° C (350° F).

2. It shall show a flash point of not less than 205° C (400° F).

3. Its specific gravity at a temperature of 25° C (77° F) shall be not less than 1.000 nor more than 1.030.

4. When tested with a standard No. 2 needle by means of a Dow penetrometer, or other penetrometer giving the same results as the Dow machine, it shall show penetrations within the following limits for the conditions stated, the penetrations being expressed in hundredths of a centimeter: 100 g load, 5 sec, at 25° C (77° F), from 90 to 100; 200 g load, 1 min, at 4° C (39° F), not less than 30.

5. Its melting point as determined by the cube method shall be not less than 50° C (122° F).

6. When 50 g of the material is maintained at a uniform temperature of 163° C (325° F) for 5 hr in an open cylindrical tin dish, 5½ cm (about 2¼ in) in diameter, with vertical sides measuring approximately 3½ cm (about 1½ in) in depth, the loss in weight shall not exceed 1% of the original weight of the sample.

The penetration of the residue, when tested as described in clause 4 with a standard No. 2 needle under a load of 100 g, for 5 sec at 25° C (77° F) shall be not less than one-half the penetration of the original material tested under the same conditions.

7. Its bitumen as etermined by its solubility in chemically pure carbon disulphide at room temperature shall not be less than 99.5%.

8. It shall be soluble in chemically pure carbon tetrachloride at room temperature to the extent of not less than 99.5% of its bitumen as determined by clause (7).

9. It shall be soluble in 86° to 88° B paraffin naphtha, at least 85% distilling between 40° and 55° C (104° and 131° F), to the extent of not less than 72% nor more than 78% of its bitumen as determined by clause (7).

10. It shall yield not less than 11% nor more than 15% of fixed carbon.

"Asphalt Cement C optional with asphalt cements A, B, D, E, and refined tars F and G.

1. The asphalt cement shall be homogeneous, free from water and shall not foam when heated to 177° C (350° F).

2. It shall show a flash point of not less than 205° C (400° F).

3. Its specific gravity at a temperature of 25° C (77° F) shall be not less than 1.030 nor more than 1.040.

4. When tested with a standard No. 2 needle by means of a Dow penetrometer, or other penetrometer giving the same results as the Dow machine, it shall show penetrations within the following limits for the conditions stated, the penetrations being expressed in hundredths of a centimeter: 100 g load, 5 sec, at 25° C (77° F), from 70 to 90; 200 g load, 1 min, at 4° C (39° F), not less than 10.

5. Its melting point as determined by the cube method shall be not less than 45° C (113° F).

6. When 50 g of the material is maintained at a uniform temperature of 163° C (325° F) for 5 hr in an open cylindrical tin dish, 5½ cm (about 2¼ in) in diameter, with vertical sides measuring approximately 3½ cm (about 1½ in) in depth, the loss in weight shall not exceed 2% of the original weight of the sample.

The penetration of the residue, when tested as described in clause (4) with a standard No. 2 needle under a load of 100 g, for 5 sec at 25° C (77° F) shall not be less than one-half the penetration of the original material tested under the same conditions.

7. Its bitumen as determined by its solubility in chemically pure carbon disulphide at room temperature shall not be less than 99.5%.

8. It shall be soluble in chemically pure carbon tetrachloride at room temperature to the extent of not less than 99.5% of its bitumen as determined by clause (7).

9. It shall be soluble in 86° to 88° B paraffin naphtha, at least 85% distilling between 40° and 55° C (104° and 131° F), to the extent of not less than 80% nor more than 88% of its bitumen as determined by clause (7).

10. It shall yield not less than 10% nor more than 14% of fixed carbon.

"Asphalt Cement D optional with asphalt cements A, B, C, E, and refined tars F and G.

1. The asphalt cement shall be homogeneous, free from water and shall not foam when heated to 177° C (350° F).

2. It shall show a flash point of not less than 205° C (400° F).

3. Its specific gravity at a temperature of 25° C (77° F) shall be not less than 1.025 nor more than 1.050.

4. When tested with a standard No. 2 needle by means of a Dow penetrometer, or other penetrometer giving the same results as the Dow machine, it shall show penetrations within the following limits for the conditions stated, the penetrations

being expressed in hundredths of a centimeter: 100 g load, 5 sec, at 25° C (77° F), from 85 to 95; 200 g load, 1 min, at 4° C (39° F), not less than 20.

5. Its melting point as determined by the cube method shall be not less than 50° C (122° F).

6. When 50 g of the material is maintained at a uniform temperature of 163° C (325° F) for 5 hr in an open cylindrical tin dish, 5½ cm (about 2¼ in) in diameter, with vertical sides measuring approximately 3½ cm (about 1½ in) in depth, the loss in weight shall not exceed 2% of the original weight of the sample.

The penetration of the residue, when tested as described in clause (4) with a standard No. 2 needle under a load of 100 g, for 5 sec at 25° C (77° F) shall be not less than one-half the penetration of the original material tested under the same conditions.

7. Its bitumen as determined by its solubility in chemically pure carbon disulphide at room temperature shall not be less than 99.5%.

8. It shall be soluble in chemically pure carbon tetrachloride at room temperature to the extent of not less than 99.5% of its bitumen as determined by clause (7).

9. It shall be soluble in 86° to 88° B paraffin naphtha, at least 85% distilling between 40° and 55° C (104° and 131° F), to the extent of not less than 67% nor more than 77% of its bitumen as determined by clause (7).

10. It shall yield not less than 12% nor more than 18% of fixed carbon.

"Asphalt Cement E optional with asphalt cements A, B, C, D, and refined tars F and G.

1. The asphalt cement shall be homogeneous, free from water and shall not foam when heated to 177° C (350° F).

2. It shall show a flash point of not less than 165° C (329° F).

3. Its specific gravity at a temperature of 25° C (77° F) shall be not less than 1.040 nor more than 1.060.

4. When tested with a standard No. 2 needle by means of a Dow penetrometer, or other penetrometer giving the same results as the Dow machine, it shall show penetrations within the following limits for the conditions stated, the penetrations being expressed in hundredths of a centimeter: 100 g load, 5 sec, at 25° C (77° F), from 140 to 160; 200 g load, 1 min, at 4° C (39° F), not less than 40.

5. When tested by means of the New York Testing Laboratory Float Apparatus, the float shall not sink in water maintained at 66° C (150° F) in less than 120 sec nor more than 180 sec.

6. When 50 g of the material is maintained at a uniform temperature of 163° C (325° F) for 5 hr in an open cylindrical tin dish, 5½ cm (about 2¼ in) in diameter with vertical sides measuring approximately 3½ cm (about 1½ in) in depth, the loss in weight shall not exceed 3% of the original weight of the sample.

The penetration of the residue, when tested as described in clause (4) with a standard No. 2 needle under a load of 100 g, for 5 sec at 25° C (77° F) shall be not less than one-half the penetration of the original material tested under the same conditions.

7. Its bitumen as determined by its solubility in chemically pure carbon disulphide at room temperature shall be not less than 93% nor more than 98%.

8. It shall be soluble in chemically pure carbon tetrachloride at room temperature to the extent of not less than 98.5% of its bitumen as determined by clause (7).

9. It shall be soluble in 86° to 88° B paraffin naphtha, at least 85% distilling between 40° and 55° C (104° and 131° F), to the extent of not less than 75% nor more than 85% of its bitumen as determined by clause (7).

10. It shall yield not less than 11% nor more than 15% of fixed carbon.

11. Upon ignition it shall yield not less than 1% nor more than 3% of ash.

"Refined Tar F optional with asphalt cements A, B, C, D, E, and refined tar G.

1. The refined tar shall be homogeneous, free from water and shall not foam when heated to 150° C (302° F).

2. Its specific gravity at a temperature of 25° C (77° F) shall be not less than 1.160 nor more than 1.200.

3. When tested by means of the New York Testing Laboratory Float Apparatus, the float shall not sink in water maintained at 50° C (122° F) in less than 140 sec nor more than 170 sec.

4. Its bitumen as determined by its solubility in chemically pure carbon disulphide at room temperature shall be not less than 95% and it shall show not more than 0.2% ash upon ignition of the material insoluble in carbon disulphide.

5. When distilled according to the tentative method recommended by Com. D-4, Am. Soc. Test. Mat. in 1911, it shall yield no distillate at a temperature lower than 170° C (338° F); not more than 7% by weight shall distill below 270° C (518° F), and not more than 20% by weight shall distill below 300° C (572° F).

6. The total distillate from the test made in accordance with clause (5) shall have a specific gravity at a temperature of 25° C (77° F) of not less than 1.000 nor more than 1.020.

7. The melting point, as determined in water by the cube method, of the pitch residue remaining after distillation to 300° C (572° F), in accordance with the test described in clause (5), shall be not more than 75° C (167° F).

" Refined Tar G optional with asphalt cements A, B, C, D, E, and refined tar F.

1. The refined tar shall be homogeneous, free from water and shall not foam when heated to 150° C (302° F.).

2. Its specific gravity at a temperature of 25° C (77° F) shall be not less than 1.200 nor more than 1.300.

3. When tested by means of the New York Testing Laboratory Float Apparatus, the float shall not sink in water maintained at 50° C (122° F) in less than 140 sec nor more than 170 sec.

4. Its bitumen as determined by its solubility in chemically pure carbon disulphide at room temperature shall not be less than 75% nor more than 90%, and it shall not show more than 0.2% ash upon ignition of the material soluble in carbon disulphide.

5. When distilled according to the tentative method recommended by Com. D-4, Am. Soc. Test. Mat. in 1911, it shall yield no distillate at a temperature lower than 170° C (338° F); not more than 10% by weight shall distill below 270° C (518° F), and not more than 20% by weight shall distill below 300° C (572° F).

6. The total distillate from the test made in accordance with clause (5) shall have a specific gravity at a temperature of 25° C (77° F) of not less than 1.030.

7. The melting point, as determined in water by the cube method, of the pitch residue remaining after distillation to 300° C (572° F), in accordance with the test described in clause (5), shall be not more than 75° C (167° F).

"Asphalt Cement H optional with asphalt cements K and L.

1. The asphalt cement shall be homogeneous, free from water and shall not foam when heated to 177° C (350° F).

2. It shall show a flash point of not less than 205° C (400° F).

3. Its specific gravity at a temperature of 25° C (77° F) shall be not less than 0.970 nor more than 1.000.

4. When tested with a standard No. 2 needle by means of a Dow penetrometer, or other penetrometer giving the same results as the Dow machine, it shall show penetrations within the following limits for the conditions stated, the penetrations being expressed in hundredths of a centimeter: 100 g load, 5 sec, at 25° C (77° F), from 60 to 75; 200 g load, 1 min, at 4° C (39° F), not less than 50; 50 g load, 5 sec, at 46° C (115° F), not more than 150.

5. Its melting point as determined by the cube method shall be not less than 80° C (176° F).

6. When 50 g of the material is maintained at a uniform temperature of 163° C (325° F) for 5 hr in an open cylindrical tin dish, 5½ cm (about 2¼ in) in diameter, with vertical sides measuring approximately 3½ cm (about 1½ in) in depth, the loss in weight shall not exceed 1% of the original weight of the sample.

The penetration of the residue, when tested as described in clause (4) with a standard No. 2 needle under a load of 100 g, for 5 sec at 25° C (77° F) shall be not less than one-half the penetration of the original material tested under the same conditions.

7. Its bitumen as determined by its solubility in chemically pure carbon disulphide at room temperature shall not be less than 99.5%.

8. It shall be soluble in chemically pure carbon tetrachloride at room temperature to the extent of not less than 99.5% of its bitumen as determined by clause (7).

9. It shall be soluble in 86° to 88° B paraffin naphtha, at least 85% distilling between 40° and 55° C (104° and 131° F), to the extent of not less than 70% nor more than 80% of its bitumen as determined by clause (7).

10. It shall yield not less than 8% nor more than 12% of fixed carbon.

"Asphalt Cement K optional with asphalt cements H and L.

1. The asphalt cement shall be homogeneous, free from water and shall not foam when heated to 177° C (350° F).

2. It shall show a flash point of not less than 205° C (400° F).

3. Its specific gravity at a temperature of 25° C (77° F) shall be not less than 1.030 nor more than 1.045.

4. When tested with a standard No. 2 needle by means of a Dow penetrometer, or other penetrometer giving the same results as the Dow machine, it shall show penetrations within the following limits for the conditions stated, the penetrations being expressed in hundredths of a centimeter: 100 g load, 5 sec, at 25° C (77° F), from 60 to 70; 200 g load, 1 min, at 4° C (39° F), not less than 18; 50 g load, 5 sec, at 46° C (115° F), not more than 270.

5. Its melting point as determined by the cube method shall be not less than 60° C (140° F).

6. When 50 g of the material is maintained at a uniform temperature of 163° C (325° F) for 5 hr in an open cylindrical tin dish, 5½ cm (about 2¼ in) in diameter, with vertical sides measuring approximately 3½ cm (about 1½ in) in depth, the loss in weight shall not exceed 1% of the original weight of the sample.

The penetration of the residue, when tested as described in clause (4) with a standard No. 2 needle under a load of 100 g, for 5 sec at 25° C (77° F) shall be not less than one-half the penetration of the original material tested under the same conditions.

7. Its bitumen as determined by its solubility in chemically pure carbon disulphide at room temperature shall not be less than 99.5%.

8. It shall be soluble in chemically pure carbon tetrachloride at room temperature to the extent of not less than 99.5% of its bitumen as determined by clause (7).

9. It shall be soluble in 86° to 88° B paraffin naphtha, at least 85% distilling between 40° and 55° C (104° and 131° F), to the extent of not less than 70% nor more than 80% of the bitumen as determined by clause (7).

10. It shall yield not less than 12% nor more than 16% of fixed carbon.

"Asphalt Cement L optional with asphalt cements H and K.

1. The asphalt cement shall be homogeneous, free from water and shall not foam when heated to 177° C (350° F).

2. It shall show a flash point of not less than 205° C (400° F).

3. Its specific gravity at a temperature of 25° C (77° F) shall be not less than 1.025 nor more than 1.055.

4. When tested with a standard No. 2 needle by means of a Dow penetrometer, or other pentrometer giving the same results as the Dow machine, it shall show penetrations within the following limits for the conditions stated, the penetrations being expressed in hundredths of a centimeter: 100 g load, 5 sec, at 25° C (77° F), from 60 to 70; 200 g load, 1 min, at 4° C (39° F), not less than 16.

5. Its melting point as determined by the cube method shall be not less than 55° C (131° F).

6. When 50 g of the material is maintained at a uniform temperature of 163° C (325° F) for 5 hr in an open cylindrical tin dish, 5½ cm (about 2¼ in) in diameter, with vertical sides measuring approximately 3½ cm (about 1½ in) in depth, the loss in weight shall not exceed 1% of the original weight of the sample.

The penetration of the residue, when tested as described in clause (4) with a standard No. 2 needle under a load of 100 g, for 5 sec at 25° C (77° F) shall be not less than one-half the penetration of the original material tested under the same conditions.

7. Its bitumen as determined by its solubility in chemically pure carbon disulphide at room temperature shall not be less than 99.5%.

8. It shall be soluble in chemically pure carbon tetrachloride at room temperature to the extent of not less than 99.5% of its bitumen as determined by clause (7).

9. It shall be soluble in 86° to 88° B paraffin naphtha, at least 85% distilling between 40° and 55° C (104° and 131° F), to the extent of not less than 67% nor more than 77% of its bitumen as determined by clause (7).

10. It shall yield not less than 13% nor more than 18% of fixed carbon.

Notes: Asphalt cements can be manufactured from Gilsonite and asphaltic oil to meet specifications A and H; from Texas asphaltic oils to meet specifications B and K; from California asphaltic oils to meet specification C; from Mexican asphaltic oils to meet specifications D and L; and from asphaltic materials from Bermudez to meet specification E. Tar cements can be manufactured from water-gas tars to meet

specification F; and from coal tars or a combination of a coal tar and a water-gas tar to meet specification G.

"**Delivery.** The asphalt cement or refined tar shall be delivered in suitable containers, far enough in advance of its use in the work to permit the necessary tests to be made. Each container shall be plainly labeled with the trade name of the asphalt cement or refined tar, name of manufacturer, gross weight and net weight. Each shipment and each carload shall be kept separate.

"**Bills of Lading.** The contractor shall furnish the engineer on or before the arrival of each shipment at or near the site of the work, bills of lading, or correct copies thereof which shall state the trade name of the asphalt cement or refined tar, and the name and address of the company manufacturing and supplying it.

"**Samples.** Samples will be taken by the engineer from each carload of asphalt cement or refined tar when delivered at the work, unless satisfactory arrangements can be made for sampling before shipment. Such samples shall be analyzed by the engineer to assure the delivery of an asphalt cement or refined tar of the specified quality and to determine, for purpose of payment, the quantity of bitumen.

"**Work Included.** Under this item the contractor shall furnish and deliver on the work at such points as directed an asphalt cement or an asphalt cement and a refined tar, which conform with the specifications heretofore mentioned. All asphalt cement or refined tar for any pavement of a given contract shall be furnished by one manufacturer and no change in type or grade of bituminous cement used in the bituminous concrete or the seal coat shall be allowed in any pavement of a given contract without written permission from the engineer.

"**Measurement and Payment.** The quantity of bitumen in the asphalt cement or refined tar, to be paid for under this item, shall be the number of tons, determined in accordance with the paragraph headed Samples, contained in the asphalt cement or refined tar placed in the pavement in accordance with the specifications and requirements, or used as directed for other purposes. The percentage of bitumen determined by an average of the analyses of the acceptable samples taken by the engineer during a given month, shall be used as the basis for payment for the asphalt cement or refined tar used during that month. Asphalt cement or refined tar that is wasted shall not be included in the measurement under this item. The price stipulated in this item shall include the cost of furnishing, hauling and delivering the asphalt cement or refined tar at points on the work where it is to be used, and all expenses incidental thereto."

U. S. O. P. R. 1918 Specifications for Bituminous Cements to be Used with a Mineral Aggregate Consisting of One Product of Broken Stone.

"**Bermudez Asphalt Cement, NA-3.** GENERAL. The fluxed native asphalt shall be homogeneous, free from water, and shall not foam when heated to 175° C (347° F):

"PHYSICAL AND CHEMICAL PROPERTIES. It shall meet the following requirements.

1. Specific gravity 25°/25°C (77°/77° F), 1.050 to 1.070;
2. Flash point, not less than 175° C (347° F);
3. Melting point, 40°C (104° F) to 50° C (122° F);
4. Penetration at 25° C (77° F), 100 g, 5 sec, 80 to 90;
5. Loss at 163° C (325° F), 5 hr, not more than 3.0%;
   Penetration of residue at 25° C (77°F) 100 g, 5 sec, not less than 40;
6. Total bitumen, soluble in carbon disulphide, not less than 95.0%;
   Inorganic matter insoluble, 1.5% to 3.0%."

"**Oil Asphalt Cement, OA-3.** GENERAL. The oil asphalt shall be homogeneous, free from water, and shall not foam when heated to 175° C (347° F).

"PHYSICAL AND CHEMICAL PROPERTIES. It shall meet the following requirements:

1. Specific gravity 25°/25° C (77°/77° F), not less than 1.010;
2. Flash point, not less than 175° C (347° F);
3. Melting point, 40° C (104° F) to 60° C (140° F);
4. Penetration at 25° C (77° F) 100 g 5 sec, 80 to 90;
5. Loss at 163° C (325° F), 5 hr. not more than 1.0%;
   Penetration of residue at 25° C (77° F) 100 g, 5 sec, not less than 50;
6. Total bitumen, soluble in carbon disulphide, not less than 99.5%;
   Organic matter insoluble, not more than 0.2%."

"NOTE: Material for any one contract shall not vary more than 0.020 in specific gravity nor more than 10° C (50° F) in melting point within the test limits above specified.

Methods of Testing. Tests of the physical and chemical properties of the asphalt cements shall be made in accordance with the following methods:

1. Specific gravity: Bul. U. S. Dept. Agr., 314, p. 5.
2. Flash point, open cup: Bul. U. S. Dept. Agr., 314, p. 17.
3. Melting point: Am. Soc. Test Mat. Tentative Standard D 36-16T, Proc. Am. Soc. Test Mat. 1916, p. 549.
4. Penetration: Am. Soc. Test Mat. Standard Test D 5-16.
5. Volatilization test: Bul. U. S. Dept. Agr., 314, p. 19, using 50 g sample.
6. Total bitumen: Bul. U. S. Dept. Agr., 314, p. 25.

"**Purpose and Use.** These specifications provide for material to be used in the construction of one-size stone bituminous concrete in the northern United States. NA-3 is intended to cover satisfactory grades of products prepared by fluxing Bermudez asphalt, and OA-3 satisfactory grades of oil asphalts prepared from Mexican, California, Texas and other petroleums.

"One-size stone bituminous concrete contemplates a mixture of the bituminous material with a crusher product passing a 1¼-in and retained upon a ½-in laboratory screen, or passing a 1-in and retained on a ¼-in laboratory screen. The bituminous material should be heated to a temperature of from 135° C (275° F) to 163° C (325° F), and the crushed stone to a temperature of from 66° C (150° F) to 121° C (250° F), before mixing. The mixture should contain from 5% to 7% bitumen. The hot mixture should be deposited in a uniform layer over a concrete or well-compacted broken stone or gravel foundation to such depth that it will yield a uniform layer 2 in in thickness after thoro rolling. A seal coat of the same bituminous material should be applied at the rate of 0.4 to 0.6 gal per yd and covered with a sufficient amount of stone chips to absorb the excess bitumen."

"**Water-Gas Tar Cement, TP-3.** GENERAL. The refined tar shall be homogeneous and free from water.

"PHYSICAL AND CHEMICAL PROPERTIES. It shall meet the following requirements:

1. Specific gravity 25°/25° C (77°/77° F), 1.150 to 1.200;
2. Float test at 50° C (122° F), 120 sec to 150 sec;
3. Total distillate by weight:
   To 170° C (338° F), not more than 1.0%
   To 270° C (518° F), not more than 10.0%
   To 300° C (572° F), not more than 20.0%
   Melting point of residue, not more than 65° C (149° F);
4. Total bitumen, soluble in carbon disulphide, 97% to 100%."

"**Gas-House and Coke-Oven Tar Cements, TP-4.** GENERAL. The refined tar shall be homogeneous and free from water.

"PHYSICAL AND CHEMICAL PROPERTIES. It shall meet the following requirements:

1. Specific gravity 25°/25° C (77°/77° F), 1.200 to 1.250;
2. Float test at 50° C (122° F), 120 sec to 150 sec;
3. Total distillate by weight:
   To 170° C (338° F), not more than 1.0%
   To 270° C (518° F), not more than 10.0%
   To 300° C (572° F), not more than 20.0%
   Melting point of residue, not more than 65° C (149° F);
4. Total bitumen, soluble in carbon disulphide, 80% to 97%.

"**Methods of Testing.** Tests of the physical and chemical properties of the refined tar shall be made in accordance with the following methods:

1. Specific gravity: Bul. U. S. Dept. Agr., 314, p. 5.
2. Float test: Bul. U. S. Dept. Agr., 314, p. 9.
3. Distillation tests: Am. Soc. Test Mat. Standard Test D 20-16.
   Melting point: Am. Soc. Test Mat. Tentative Standard D 36-16 T, Proc. Am. Soc. Test Mat., 1916, p. 549.
4. Total bitumen: Bul. U. S. Dept. Agr., 314, p. 25.

"**Purpose and Use.** These specifications provide for a material to be used in the construction of one-size stone bituminous concrete in the northern United States. TP-3 is intended to cover refined water-gas tar products, and TP-4 refined gas-house and coke-oven tar products.

"One-size stone bituminous concrete contemplates a mixture of the tar with a crusher product passing a 1¼-in screen and retained upon a ½-in laboratory screen, or passing

a 1-in and retained on a ¼-in laboratory screen. The tar should be heated to a temperature of from 107° C (225° F) to 135° C (275° F) and the crushed stone to a temperature of from 66° C (150° F) to 121° C (250° F) before mixing. The mixture should contain from 5% to 7% bitumen. The hot mixture should be deposited in a uniform layer over a concrete or well compacted broken stone or gravel foundation to such depth that it will yield a uniform layer 2 in in thickness after thoro rolling. A seal coat of the same tar or of hot asphalt (specification OA-6) should then be applied at the rate of 0.4 to 0.6 gal per sq yd and covered with a sufficient amount of stone chips to just absorb the excess bitumen."

Bituminous Cements for Southern United States. BERMUDEZ ASPHALT CEMENT specifications same as NA-3, except that the penetration limits at 25° C (77° F) are 70 and 80; the penetration of residue at 25° C (77° F), not less than 35; and the limits for inorganic matter insoluble, 2.0 and 3.5%.

OIL ASPHALT CEMENT specifications same as OA-3, except that the penetration limits at 25° C (77° F) are 70 and 80; and the penetration of residue at 25° C (77° F), not less than 45.

WATER-GAS TAR CEMENT specifications same as TP-3, and GAS-HOUSE AND COKE-OVEN TAR CEMENT specifications same as TP-4, except that the limits for the float test are 150 and 180 sec.

U. S. O. P. R. 1918 Specifications for Asphalt Cements to be Used with Modified Topeka Aggregate. For specifications covering the aggregate see Art. 8.

Bermudez Asphalt Cement, NA-5, for Northern United States. Same as specifications NA-3, except that the limits for melting point are 45° C (113° F) and 55° C (131° F); the penetration limits at 25° C (77° F), 60 and 70; the penetration of residue at 25° C (77° F), not less than 30; the total bitumen, not less than 94.5%; and the limits for inorganic matter insoluble, 2.0 and 3.5%.

Bermudez Asphalt Cement, NA-6, for Southern United States. Same as specifications NA-5, except that the penetration limits at 25° C (77° F) are 50 and 60; the penetration of residue at 25° C (77° F) not less than 25; the total bitumen, not less than 94%; and the limits for inorganic matter insoluble, 2.5 and 4.0%.

Oil Asphalt Cement, OA-5, for Northern United States. Same as specification OA-3, except that the penetration limits at 25° C (77° F) are 60 and 70; and the penetration of residue at 25° C (77° F), not less than 40.

Oil Asphalt Cement, OA-6, for Southern United States. Same as specification OA-5, except that the specific gravity must be not less than 1.020; the penetration limits at 25° C (77° F), 50 and 60; and the penetration of the residue at 25° C (77° F), not less than 30.

Purpose and Use. These specifications provide for asphalt cements to be used in the construction of graded fine aggregate bituminous concrete, and specifications OA-6 for an asphalt cement which may also be used as a seal coat on tar macadam or tar concrete pavements. NA-5 and NA-6 are intended to cover satisfactory grades of asphalt cements prepared by fluxing Bermudez asphalt, and OA-5 and OA-6 satisfactory grades of asphalt cements prepared from Mexican, California, Texas and other petroleums.

"The asphalt should be heated to a temperature of from 135° C (275° F) to 163° C (325° F), and the crushed stone to a temperature of from 121° C (250° F) to 149° C (300° F), before mixing. The mixture should contain from 7% to 11% bitumen. The mixture should be deposited in a uniform layer over a concrete or well compacted broken stone or gravel foundation to such a depth that it will yield a uniform layer 2 in in thickness after thoro rolling. A seal coat should not be necessary on this type of pavement."

Philadelphia, 1917 Specification for Warrenite Cement:

"General. The asphaltic cement shall be known as Warrenite Cement and shall be uniform in quality and shall contain no products obtained from coal, water-gas or oil-gas tar. It shall not be affected by water, and shall comply with the following tests:

"Penetration. The penetration at 25° C (77° F), measured by a No. 2 needle weighted with 100 g for 5 sec, shall be between 5 and 7 mm.

"Solubility. The cement shall be soluble in cold carbon disulphide, CS_2, to the

extent of at least 96%. The amount of cement which is soluble in cold carbon tetrachloride, CCl_4, shall be at least 98.5% of the amount of pure bitumen soluble in cold carbon disulphide. This test shall be made by the standard methods in subdued lights. The amount of the cement which is soluble in Pennsylvania naphtha at 88° B shall be between 72 and 84% of the amount of bitumen which is soluble in cold carbon disulphide.

"**Brittleness, Ductility and Evaporation.** The cement shall not be brittle at 13° C (55° F) when tested according to the following method: The test piece shall be a cylindrical rod ¼ in in diameter and 4 in in length and composed of cement of the same penetration as used in the mixture. The rod shall be supported on two grooved wheels 1 in diameter at bottom of groove, placed 1⅞ in apart, center to center. A pitman, consisting of a ¼-in sq brass rod and weighted to 5 lb, shall be so placed in the machine as to descend vertically directly over the center of test piece, and is clamped in this position with the lower end of the pitman, which is grooved to fit the ¼-in test piece, just touching the test piece. The test piece shall be brought to and maintained at the desired temperature for 5 min before testing. In order to maintain constant temperature while testing, the whole machine shall be submerged in water at the desired temperature. When the pitman is released by the clamp it will either break the test piece or bend it. If the former, the temperature of test piece and apparatus shall be raised 0.56° C (1° F) and test repeated until the actual brittle point is determined. Care must be observed to maintain test piece and apparatus 5 min at each temperature before testing. The cement, of a penetration as used in the mixture, shall show a ductility of at least 20 cm when tested according to the District of Columbia method. Twenty grams of cement, when placed in a flat-bottom dish 2½ in in diameter and heated for 5 hr at 163° C (325° F), shall not lose more than 2½% by weight and the penetration of the residue, when tested with a No. 2 needle weighted with 100 g for 5 sec, shall be not less than 50% of the original penetration of the cement.

"**Cementing Strength.** The cement, when tested at 15° C (60° F), according to the following method, shall show a cementing strength of at least 2500 g, this being the total weight in grams required to break a pat of asphaltic sand mixture consisting of the following: Asphaltic cement to be tested, 8.0%, sand passing a number 30 and being retained on a number 50-mesh sieve, 92.0%. The pat shall be mixed hot and compressed into a mold to take a pat 2½ in in length, 1 in in width and ½ in in thickness. The test shall be made by placing the pat horizontally across the top edges of two ⅛-in brass plates set on edge, so that the area of the pat between the supports shall be 1 sq in. The pat shall then be acted upon by a T shaped pitman bearing down upon the pat midway between the supports. The weight on the pitman shall be increased at a uniform rate from zero to a weight sufficient to break the pat, and the final weight shall be that given in the report."

For additional specifications for bituminous cements to be used with mineral aggregates of bituminous concretes of Classes A, B and C, see Art. 17.

CONSTRUCTION

11. Mixing Plants and Tools

To meet the demand for mixing plants with which various types of mineral aggregates can be economically heated and mixed with bituminous cements, several machines have been designed in the United States. Requirements which plants should fulfil vary to a considerable extent, due to the different kinds of aggregates and bituminous cements employed.

Tools. See Sect. 17, Art. 13.

Plants for Hand Mixing. A plant for hand mixing of unheated aggregates with hot bituminous cement consists of a mixing platform, three or four heating kettles, long-handled shovels, long-handled dippers, and small tools. Sheet-iron and wooden platforms have been used, but the latter, when consisting of two sections, is preferred, as it can be used more efficiently and is more easily moved. A two-section wooden mixing board should be made of 2-in plank. Each section should be 8 ft long and 8 ft wide.

The kettles should be of such shape and size as will enable them to be easily moved. No kettle, however, should be used which will not hold 150 gal of bituminous cement.

Cement-Concrete Mixers. Unheated broken stone has been mixed with tars (see Art. 12) or heavy asphaltic oils in the ordinary type of concrete mixer. Asphalt cements of low penetration at normal temperatures cannot be mixed with unheated aggregates in this type of plant, as it is generally impracticable to coat the unheated broken stone with the hot asphalt cement. This class of mixers should not be used for the construction of asphaltic concrete pavements unless the aggregate is heated in rotary driers.

Cement-Concrete Mixers with Heating Devices. There are several different types of this class of mixing plants in current use. In one type, the heat, in the form of hot air, is passed into the mixer by means of a large iron pipe, which runs from the fire-box to the outlet end of the mixer. A second type consists of a cylindrical mixer mounted on a four-wheeled truck; heat is obtained from a hot-air jacket entirely surrounding the cylinder except on the ends, and by means of a kerosene torch inserted within the drum. In a third type, hot air obtained by the combustion of oil in air is used to heat the mineral aggregate in the mixing chamber; after the aggregate is heated, the bituminous cement is added. A fourth method of utilizing concrete mixers is to use a rotary drier, as a part of the plant, for drying the aggregate.

Driers, Storage Bins, Weighing Devices, and Mixers. In a complete plant for the manufacture of bituminous concrete, the aggregate is carried by bucket-elevators to rotary driers, where it is dried and the dust exhausted; from the drier the aggregate is raised by elevators to storage bins or to screens from which the aggregate, in several sizes, falls into storage bins; when required the aggregate is drawn from the bins to a weighing device, and from there deposited into a mixer. Such plants are also equipped with bituminous cement heating tanks and weighing buckets.

Details of Plants and Methods of Operation. Certain essential features of plants for mixing different types of bituminous concretes are discussed in Arts. 12, 14 and 16. For comprehensive descriptions and methods of operation of several types of portable plants, especially designed for mixing bituminous concretes of Classes A, B, and C, see (63). Description of some plants and methods of operation are included in this Article, and in Arts. 12, 14, and 16. Plants, especially designed for the manufacture of sheet-asphalt binder and surfaces mixtures, are fully described in Sect. 17, Art. 13, and their operation and inspection explained in detail and discussed in Sect. 17, Arts. 14 and 16.

Specifications for Mixing Plant for Class B or C Aggregates, by Kirschbraun (48h). "The paving plant shall be of an approved type, properly adapted for producing the character of mixture hereinafter described. It shall consist of separate units for melting and preparing asphaltic cement, a drier for heating mineral aggregate, a screen and storage bin, having at least two compartments whereby the mineral aggregate may be separated by means of a 6 or 8-in screen into two sizes, that passing thru the screen being collected in one compartment, while the rejection is collected in another compartment. Plant shall further be equipped with the necessary devices for weighing separately the fine and coarse aggregate from each compartment of the storage bin. An asphalt cement bucket shall be provided with scales attached in order that the amount of asphaltic cement which is put into the mixture may be properly gauged. The mixing unit shall consist of a twin pug-mill mixer or its equivalent with blades so spaced as to produce a thoroly homogeneous mixture."

Type of Plant Required for Topeka Mixture, by Richardson (57e). "If the mineral

aggregate as it comes heated from the drums is collected in a single bin, segregation takes place. The particles of stone are not uniformly distributed in the bin, and they are still further separated in drawing a charge from the bin to the measuring box. The result is a lack of uniformity in the grading of the mineral aggregate in the mixture as it is sent to the street. This may be illustrated by data showing the composition of a surface mixture produced in this way. In a locality where a rather extended piece of construction was carried out, involving the analysis of 16 samples, the mixture varied as shown by the following figures:

Bitumen	7.7%		9.8%	
200-mesh	11.8%		11.7%	
80-mesh	6.5%		8.0%	
40-mesh	22.5%		39.0%	
10-mesh	22.0%		18.0%	
4-mesh	5.5%	30.0%	4.0%	13.5%
2-mesh	24.5%		9.5%	
	100.0%		100.0%	

"To avoid results such as are illustrated by the previous figures, a plant should be provided in which proper screens separate the hot mineral aggregate into coarser and finer portions which are collected in separate bins. Under such conditions the proportion of coarse to fine aggregate can be better regulated by weighing the two components separately. The grading of a surface mixture turned out at a plant providing such facilities is shown by the following figures:

Bitumen	8.2%		8.1%		8.9%		8.9%	
200-mesh	10.3%		7.9%		9.6%		9.6%	
80-mesh	9.0%		10.0%		8.0%		7.5%	
40-mesh	24.5%		23.0%		24.5%		23.0%	
10-mesh	20.0%		19.0%		20.5%		18.0%	
4-mesh	15.5%	28.0%	20.0%	32.0%	15.5%	28.5%	15.5%	33.0%
2-mesh	12.5%		12.0%		13.0%		17.5%	
	100.0%		100.0%		100.0%		100.0%."	

Use of Cement-Concrete Mixer with Heating Devices for Mixing Topeka Bituminous Concrete, by Drowne (17c). "During the summer of 1912, the writer supervised the construction of a Topeka pavement on the Service Test Road in Philadelphia, on which a portable mixing plant of small type was used. This mixer is known commercially as the Rapid Heated Mixer. Essentially, the machine consists of a four-wheeled truck; at one end of which is mounted a boiler and engine, and at the other a small cylindrical rotary mixer. Between the boiler and the mixer is a platform on which the loading is done. The mixing drum is surrounded with a hood, furnishing a heating space of about 3 in between the shell of the latter and the mixer. The heat for this hood is furnished by a coal fire directly under the mixer. Additional heat is obtained from a kerosene torch which may be inserted within the mixing drum. A vertical blade running spirally around the inside of the drum serves to lift the material from the bottom and carry it to the top of the mixer, as the latter revolves. The material then falls to the bottom, and the same operation is repeated. The discharge spout is fixed in the center of the drum at the rear of the machine. The capacity of the mixer is 12 cu ft or a batch of about 1300 lb, including the bituminous cement.

"The various materials were taken from the stock piles in wheelbarrows to the loading platform and dumped into the mixer. The kerosene torch was then inserted within the drum, and, as the mixer revolved, the material cascaded thru the flame of the torch and was heated to a temperature of about 100° C (212° F). When this temperature was reached, the torch was withdrawn, and the asphalt cement, which was heated to about 177° C (350° F), was poured in. A cover was then placed over the opening in the loading end of the mixer. The batch was allowed to mix with the asphalt for from 1 to 2 min, at the end of which time a perfect mix was secured having a temperature of 121° C (250° F).

"The output of the machine varied, depending on the dryness of the mineral aggregate. On an average, from 4 to 5 batches were mixed per hr. When the materials

were warmed before being put in the mixer, 6 batches per hr were mixed for 1 or 2 hr, or as long as the warm material lasted. One batch of material would lay about 5 sq yd of pavement, 2 in thick when rolled. The pavement was constructed on a macadam foundation, and there was some loss, due to the material being compressed into the voids of the surface. If laid on a concrete foundation, one batch would probably have made a somewhat greater yardage. The manufacturers of this machine claim an output of 250 sq yd per 10-hr day per machine. It is generally recommended that these machines be used in pairs. It takes from 6 to 12 min to bring the material up to the proper temperature before adding the asphalt cement. If only one machine is used, and 4 or 5 batches per hr are mixed, the time required for each batch is from 12 to 15 min, therefore, considerable time is wasted by the men working around the machine. If the machines are used in pairs, the men can be kept busy practically all the time. It is the only economical way to use machines of this type. The output of two of them in a 9-hr day would be about 360 sq yd.

"If the cost of labor is $2 per day, 7 laborers being required, and 1 engineer at $3.50 per day, the labor cost of the operation would be about 4.8 cents per sq yd on a basis of 360 sq yd per day. The cost of coal, kerosene for the torch, depreciation of the machine, and supervision, would add probably about 4.5 cents, making a total cost of 9.3 cents per sq yd."

Bitulithic Plant and Its Operation by Perkins (54). "The operation of a semi-portable Bitulithic plant is as follows: The raw materials, namely, crushed stone, screenings, and sand, are fed from the storage piles at the rear of the plant into the cold stone elevators, are heated in the driers, then elevated to the rotary screen, which is enclosed in a screen house to prevent the dust scattering over the neighborhood. This screen consists of the several sections which are required to separate the mineral aggregate into the various sizes. The hot stone passing each of these screen sections drops into its compartment in a sectional bin and is thus kept separate from other sizes. The boxman weighs out the amount of each size required into a weigh-box supported on platform scales with a multiple beam which enables him to weigh each size separately and accurately. It is impossible to formulate a standard screen test or rule as to just what proportion of each size particle of mineral aggregate is required to produce the maximum density or minimum of voids, because the stone from different quarries crush into different shapes. By following the best practice under the Warren patents as described, the resulting combination of varying sizes of mineral aggregate will contain approximately 12% of voids to be filled with bitumen. While the weighing is taking place the mixer-man has filled the bitumen bucket with the required weight of Bitulithic cement by dipping from the melting tanks, the weight of bitumen being accurately measured by scales on the bucket carrier. The bitumen and mineral aggregate are then emptied into the mixer and thoroly mixed until all particles are completely coated and the mass has been transformed into a uniform bituminous concrete, when the slide under the mixer is opened and the batch dropped into the wagon waiting under the platform.

"A standard one-car railroad Bitulithic paving plant embodies all of the features of the semi-portable type and in addition has the advantage of being built on a single steel car and therefore can be more quickly erected ready to run after arrival at the destination. In addition to this, the mixing platform overhangs the side of the car, so that if the ground surrounding the plant will allow it, the wagons can be driven under the mixer from the rear, thus avoiding the delays due to backing under. There are three large kettles, two for melting and one, next to the mixer, for use as a dipping kettle, this kettle being covered and provided with an air-tight manhole cover so that the Bithulithic cement may be forced with compressed air from it to the bitumen weigh-bucket. The dial of the scales has two movable stops which are placed at the proper points for the weight of the bucket empty and full, which enables the plant foreman to tell at a glance whether the mixer-man is weighing accurately or not. These scales and the stone scales are tested daily with three standard test weights in order to detect as soon as possible any lack of adjustment."

Warrenite Plant and Its Operation by Perkins (54). "While the mixture produced by these plants is much like Bitulithic, the methods by which it is obtained are radically different from those in use with the Bitulithic plants. The crushed stone, screenings and sand are placed in separate piles, and the required proportion of each size as previously determined by laboratory test is measured into the drying section of the

plant and there remains until dried. One full batch of mineral aggregate measured in this manner is fed into the elevator and raised to the hopper. After the entire batch is in the hopper, the gate in the chute allows it to descend into the heater drum, which is heated by an oil flame thru the combustion chamber. While the batch is being heated it is slowly forced forward by spirals inside the drum towards the mixing chamber. When it is hot enough a gate or chute suspended between the heating and mixing chambers of the drum is tilted and conveys the entire batch into the mixing chamber, where it is thoroly mixed with Warrenite cement poured in thru a funnel above the platform. The bitumen is weighed accurately in a bucket on spring scales, the same as in a Bitulithic plant. When the batch is mixed it is delivered into the wagon by another tilting chute at the forward end of the mixing chamber. While one batch is going thru this process, other batches have been successively started, so that at any one moment there are, one batch in the mixer, one in the heater, one in the hopper, and one being measured in the wheelbarrows; yet on account of the design of the plant each batch is kept entirely separate and distinct from every other and for that reason it is possible to control the mixture and keep the proportions of the various sized particles of the mineral aggregate constant and uniform."

12. Construction of Class A Pavements

The methods of mixing and laying Class A bituminous concretes vary dependent upon the mixing plant employed, the characteristics of the aggregate and bituminous cement used, such local conditions as traffic, availability of skilled labor, etc, and the type of pavement constructed.

Hand Mixing. Bituminous concrete of Class A may be manufactured by hand mixing, using unheated or heated aggregate provided that a bituminous cement is used, which, when heated to a proper temperature, may be easily incorporated with the aggregate so that each particle is thoroly coated. Practice has demonstrated that hand mixing of unheated aggregates and coal tar, water-gas, or cut-back asphalt cement is practicable. If heated aggregates are used, the range of usable bituminous cements is, of course, increased. In connection with hand mixing, however, usually only crude methods of heating have been employed, such as the use of hot plates or pipes upon which the aggregate is placed and agitated from time to time by hand methods. These crude methods of heating should not be employed as the general result is uneven heating of the aggregate and, in many cases, burning of the batches of bituminous concrete due to overheating of the aggregate. Generally speaking, crude methods and appliances are used with hand mixing, and it should be realized that this method of manufacture is a makeshift and should only be used under special conditions, as on short sections or where it is impracticable to use a mixing plant. With the multiplicity of plants in use and their general availability, few are the cases where hand mixing is justifiable.

The ordinary method of using the hand mixing method for the construction of pavements on highways outside of urban districts is as follows: The aggregate, which should be clean and dry, is deposited upon mixing boards placed on the foundation course a few feet in front of the bituminous concrete in place. In using a two-section mixing platform, the aggregate should be deposited at the end of the platform farthest from the bituminous concrete in place. The bituminous cement, after having been heated to the proper temperature in portable kettles, is distributed over the pile of aggregate by means of long-handled dippers. Mixing with long-handled shovels is then begun, the coated aggregate being turned over towards the end of the platform nearest the bituminous concrete in place. During the process of mixing, more bituminous cement is added until the total amount per 1 cu yd of loose aggregate is from 15 to 21 gal, the proper amount being

dependent upon the composition and kind of aggregate, and grade of bituminous cement. After the aggregate is thoroly coated, it is deposited in place by shovels. The bituminous concrete should not be cast onto the foundation, but each shovelful should be carried and deposited next to bituminous concrete in place. Before the next load of aggregate is dumped, the section of the mixing platform nearest the bituminous concrete should be transferred to a position adjoining but just ahead of the other section. For further discussion of hand mixing methods, see (53a) and (61b).

Machine Mixing. The details of the operation of mixing bituminous concretes will depend, to a certain extent, upon the type of machine employed.

CEMENT-CONCRETE MIXERS have been used with both unheated and heated aggregate. In the former case, the remarks relative to adaptability of the hand mixing method apply with equal force. If independent rotary driers constitute part of the plant equipment, excellent results may be secured with any of the bituminous cements used with Class A aggregates. Generally, the operation of a plant made up of independent units will not be as efficient or economical as when portable combined plants are used. Very good results have been obtained, with careful supervision, by using cement-concrete mixers with heating attachments consisting of hot air blasts or torches. It should not be expected that as uniformly heated aggregate or as high temperatures can be obtained as with rotary driers.

Except in the case of the use of an independent rotary drier unit, the aggregate in general is measured in wheelbarrows. The bituminous cement is measured by volume or weight, dependent upon the plant accessories. After the aggregate has been heated to the desired temperature, the bituminous cement is added to the aggregate in the mixing chamber. The mixture is agitated until each particle is thoroly coated. The bituminous concrete is discharged by the mixer into wheelbarrows, wagons, or trucks, transported to the site of the pavement under construction, and deposited on dumping boards.

Use of Cement-Concrete Mixers in Rhode Island by Poore (17c). "Refined coal tar was used as a binder, this material being shipped in tank cars to the nearest railway station, where it was steam-heated and barreled by the contractor. During the height of the season, 18 mechanical mixers were in operation, laying daily a total of 3000 ft of 14-ft road surface, 2 in thick. The type of mixer generally used was one manufactured by the Municipal Engineering and Contracting Co. It is similar to the ½-yd cube batch cement-concrete mixer, and has an oil torch heating device for use when bituminous concrete is mixed. The machine is mounted on four wheels for transportation. It consists of a revolving iron box, mounted on its diagonal axis, and driven with direct gearing by the steam engine mounted on the same frame. The mixed material is discharged by tipping the cube, and the mixing chamber is loaded with a sliding skip operated by a small cable hoist. An air compressor for supplying the oil torch is belted to the engine. Common fuel oil under air pressure forms a blast in the center of the mixing chamber sufficient to dry the mineral aggregate and expedite the work during cold weather. As the specification called for a cold mix, the blast was not necessary thruout the day's work.

"The plants were operated in two ways; either as a portable plant moving along the road each day, or as a stationary unit at the stone crusher. The first method was followed where the work consisted of scarifying the old macadam and adding a new 2-in bituminous concrete surface. Set-ups were made at the intervals covered in a day, usually about 200 ft. A 12 by 12-ft dumping board was used under the loading skip, on which to dump the broken stone hauled from the railroad siding or stone crusher. The mixer was placed on planks in the center of the road, being hauled ahead by the steam roller at the end of the day. Two 150-gal portable kettles provided sufficient hot bituminous material. The proper quantity for a batch was measured out by hand and carried in buckets from the side of the road to the loading chute. Six iron barrows, well oiled to prevent the coated stone from sticking, were used in

carrying the hot mixture to the road, where it was raked out to the required depth.

"When the mixer was used as a permanent unit at the stone-crushing plant, the mixer platform was built at the same elevation as the bottom of the stone bins, and from the latter the stone could be discharged directly to the loading skip. To allow the uncoated stone for the foundation course to fall by gravity into wagons, it was necessary to leave an intervening space of 7 or 8 ft between the stone bins and the mixer platform. Many of the mixers ran three ½-cu yd batches in from 10 to 15 min. A 1½-cu yd bottom-dump wagon was placed to receive these three batches, and then hauled to the road, a 2-mile haul often being economical. There was no chilling of the mixture. A larger kettle was used at the stationary plants than on the resurfacing work. The buckets of hot bituminous material were handed from the ground by the kettleman to the man on the raised mixer platform, and he emptied them into the mixer chute. One engineer, one helper, one loading man, and one kettleman were required for the mixer when in operation. Practically 600 sq yd of 2-in surface were turned out per day at each plant."

Stationary, Semi-Portable and Portable Self-Contained Mixing Plants of many types have been successfully employed in the manufacture of Class A bituminous concretes. Naturally the most economical and efficient work has been accomplished by plants especially adapted for mixing Class A aggregates. Generally, on highway work outside of urban districts, the portable plant proves most satisfactory. Dependent upon the plant accessories, the aggregate is measured by volume or weight before being dried or by weight after drying, the latter being preferable. The aggregate is usually dumped into bucket elevators, which discharge into rotary driers. In the best types of plants, the heated aggregate is then raised by bucket elevators and discharged into a small storage bin. As desired, the heated aggregate is drawn from the storage bin and allowed to fall directly into the pug mill mixer or, preferably, first into a weighing box. The bituminous cement is weighed in scales on the mixing platform and then dumped into the mixer. After thoro mixing, the bituminous concrete is usually discharged into a wagon or truck, which the plant arrangement permits to be placed directly beneath the mixer.

Comparison of Mixing Methods by Warren (71a). "The mixing methods are of two general classes as to hardness of bitumen, known as cold process and hot process, and two classes as to method of mixing, known as hand mixing and machine mixing, which will be treated in the order named. The cold process means the use of a mixture of stone and bitumen of such a character that the ingredients can be mixed and laid without artificial heat, that is, at the temperature of the air. This necessitates the use of bitumen of a character which is liquid when cold and is necessarily deficient in cementing strength unless the bitumen is made liquid by the use of a volatile temporary liquefier which will evaporate soon after the roadway surface is laid. The cold process is also necessarily subject to the weakness that the moisture has not been evaporated from the aggregate before adding the bitumen, which seems to be bad practice to say the least. In the writer's judgment, other things being equal, the hot process gives the best results; but it is necessarily more expensive both on account of the more or less expensive plant required to heat and mix the ingredients, but also the greater amount of labor required to heat and roll the much tougher, denser and harder surface mixture. The hot process has the great advantage of providing a surface which is set hard as soon as compressed and chilled to the temperature of the air.

"Hand Mixtures have the following advantages over machine mixtures:

1. Comparatively little expense of plant installation on account of which it is applicable for use on roadways of less area than practicable by machine methods.

2. No cost of fuel and consequent saving.

3. Some writers say machine mixing labor is less than hand mixing, but, taking all items of cost including plant installation and delivery of materials to and from the mixing plant, and labor for mixing and laying, into consideration, the writer believes as a rule the reverse is the real condition.

"The disadvantages of the hand mixing processes are:

1. Manifestly less thoro mixing and less accurate proportioning and uniform distribution of ingredients and consequently greater variableness of results than with a properly constructed mixing and heating plant.

2. Because of greater ease in hand mixing, a marked tendency toward use of softer bitumen.

3. Impracticability of getting a thoro mixture without more power than can be executed by hand mixing if the combination of ingredients are as dense as they should be to produce the best results.

"MACHINE MIXING methods may be sub-divided into several classes as follows:

1. Mixing without accurately proportioning or heating ingredients for which ordinary concrete mixers, either of the continuous or batch types, will answer. This method has the advantage of least expense in plant and labor which, in the writer's judgment, is very much more than counterbalanced by the disadvantages of using bitumen of a grade so soft as to be liquid at normal temperature and of less accuracy and uniformity of results.

2. Mixing by heating without accurately proportioning the ingredients which, in the writer's judgment, is better than the last named method but still inherently defective.

3. Using a well planned mixing and heating machine specially constructed for the purpose, which will produce the following essentials to a maximum degree of success:

a. Uniformity and accuracy of proportioning of ingredients both as to varying sizes of mineral aggregate and amount of bitumen.

b. Sufficient heat in the ingredients when mixed and laid in the work to evaporate moisture and permit the use of bitumen hard enough to furnish a true binder.

c. When compressed in the work a solid, dense, voidless, dry, bituminous concrete wearing surface which will to the greatest possible extent prevent penetration of moisture, the enemy of all road surfaces, and withstand the troublesome automobile and other traffic without shifting or presenting undesirably soft surfaces."

Details of Heating Aggregates, Bituminous Cements and Bituminous Concretes. See Am. Soc. C. E. Spec. Com. recommendations, in this Article, and Art. 8 for requirements covering heating of different aggregates and bituminous cements, and temperatures at which bituminous concretes should be laid.

Hauling Bituminous Mixtures by Mullen (49c). "Whether wagons or auto trucks will prove most economical is always a local problem. The auto trucks are good for long hauls with steep grades, but there is frequently greater economy in the wagon for short hauls with flat grades. Provisions should be made for the rapid loading and unloading of either, but especially the automobiles. The author remembers figuring on one job that cost 1 cent a minute to have a horse and wagon of 3 tons capacity stand for its load, and 5 cents per minute for a 5-ton auto truck. After that, a loading hopper was built.

"Canvas covers on the trucks are very good at all times, and especially in chilly weather when the crust of the mixture would otherwise become too stiff for proper raking. They should be so arranged that there is a 3 or 4-in air space between the cover and the load, however, as this not only saves the cover but also provides much better protection for the hot mixture.

"One cent per inch yard mile is a good formula to remember when considering the cost of hauling asphalt paving mixtures. That is, it cost about 1 cent to haul enough mixture to lay 1 sq yd of asphalt pavement 1 in thick and weighing about 100 lb on a street 1 mile from the mixing plant. Multiply 1 cent by the thickness in inches of the pavement, and that by the number of miles between the plant and the job. This is a rough and ready rule that should not be used for a bidding estimate, but it will help in quickly considering the comparative advantages of various available plant sites. It was the basis of a large asphalt hauling contract in New York City, at a time when team hire was $6 a day."

Laying. In cases where neither curbs, gutters nor edgings are used, thoroly compacted shoulders are constructed. To serve as definite boundaries and to prevent the bituminous concrete from being forced out over the

shoulders during rolling, 2-in planks may be placed on the shoulders at the edges of the roadway and allowed to remain until after the seal coat is applied.

After the bituminous concrete has been deposited on the foundation course, it should be uniformly spread by raking to a depth such that when compacted the wearing course will have the desired thickness, which is usually 2 in. For stiff bituminous concrete mixtures, heated shovels should be used for depositing the mix on the foundation course and hot rakes for spreading the bituminous concrete. Care should be taken to see that shovels and rakes are not overheated, as otherwise the mix may be burnt. Usually the back of the rakes should be used to spread the mix uniformly. If the tines are used for this purpose, the larger stones of the mix may be segregated in the surface of the wearing course.

After being uniformly distributed, the bituminous concrete is rolled while it is still warm and pliable. The rolling should begin at the edges and work towards the center. Rolling should continue, without interruption, until all roller marks disappear and the surface shows no further compressibility. Any places which the roller cannot effectively compress should be compacted with hot iron tampers. Excellent results can be secured by the use of tandem rollers, weighing between 10 and 12 tons and having a compression under the rear roller of from 250 to 350 lb per lin in of roll. Equally good results have been obtained by using a 5 to 8-ton tandem roller to shape up the wearing course, and a 12-ton three-wheeled roller for the thoro compaction of the bituminous concrete. In order to prevent ashes from dropping onto the bituminous concrete, each roller should be provided with an ash pan.

The surface of the compacted wearing course should be tested for irregularities and depressions. A 4-ft straight edge may be satisfactorily used for this purpose. When laid longitudinally on any part of the surface, or diagonally or transversely on each half of the roadway, in case a two-plane section is used, there should be no depressions over ⅜ in in depth. Should depressions or other irregularities be found which require correction, the tines of a rake should be used to loosen up the bituminous concrete if the mix is of such composition that it can be used to fill the depressions. If, however, the maximum sized particles are 1 to 1¼-in, the areas of the wearing course, where the depressions occur, should be removed and freshly mixed bituminous concrete used in making the repairs.

During the placing and compaction of the bituminous concrete and until after the completion of the seal coat, shoulders and adjacent driveways should be kept watered or oiled to prevent dust from accumulating on the surface of the bituminous concrete. Even a thin layer of dust on the surface of the wearing course materially decreases the strength of the bond between the seal coat and the bituminous concrete.

Seal Coat. After the wearing course has been rolled sufficiently so that the wheels of the roller do not make any creases, a coat of bituminous cement is applied to the surface. The seal coat should not be applied unless the surface is clean and absolutely dry. In many cases the bituminous concrete will have to be thoroly swept before the application of the seal coat. From ½ to 1 gal per sq yd of bituminous cement should be used, the requisite amount varying directly with the openness of the compacted bituminous concrete surface and the kind of bituminous cement used.

The best method of constructing a uniformly distributed seal coat is to use a hand-drawn gravity distributor or a hand-drawn pressure distributor;

for descriptions of which, see Sect. 14, Art. 6. If the gravity distributor is used, it should be followed by a man pushing a rubber or leather squeegee. The squeegee should have a width greater by from 4 to 6 in than the width of the sheet of bituminous cement as it falls from the distributor. By being kept from 2 to 4 in back of the sheet of bituminous cement, a very even distribution may be easily obtained. It is not economically practicable to use large distributors of the types employed in the construction of bituminous surfaces as it is not advisable to leave long sections of bituminous concrete exposed, due to the probability of the interstices becoming filled with dirt and the surface covered with a thick film of dust. The manner of applying the seal coat also may be as follows: The heated bituminous cement is placed in an iron-bodied wheelbarrow, the barrow being kept practically full of the hot cement while the same is being used. The bituminous cement is applied to the bituminous concrete surface from the wheelbarrow by means of brooms in the amount specified. Altho very fair results have been obtained by this method, it is not recommended, as the results secured with distributors are superior, especially from the standpoint of uniformity of distribution of the bituminous cement.

As soon after the application of the bituminous cement as possible, a thin layer of dry, clean chips should be uniformly spread over the coat of bituminous cement, the total amount of chips being preferably distributed in two applications. A safe rule to follow is not to allow the application of the chips to lag more than 20 ft behind the placing of the bituminous cement. In case the men distributing chips are close upon the application of bituminous cement, care must be taken to prevent the chips from being applied upon the wearing course of bituminous concrete. The chips should be rolled at least twice in order to force them into the interstices of the surface and secure the maximum bond with the bituminous cement.

Weather Conditions. It is, of course, impracticable to lay bituminous concrete during damp or rainy weather as the foundation must be dry before the bituminous concrete is deposited thereon and the wearing course surface must be dry before the application of the seal coat of bituminous cement. It is not advisable to lay bituminous concrete when the air temperature in the shade is below 10° C (50° F), due primarily to the difficulty in securing a thoroly compacted wearing course. After rains and during damp weather, a portable cascading or rotary drier will be found very useful for drying piles of wet chips. It is also advisable to have at hand several waterproof covers for use in covering piles of chips, the section of bituminous concrete upon which the seal coat has not been applied, and a short section of the foundation in advance of the bituminous concrete in place. The use of covers, in the manner indicated, will materially reduce delays caused by wet weather.

Conclusions, Spec. Com. Mat. Road Cons., Am. Soc. C. E. (17e). "HEATING AGGREGATES AND BITUMINOUS CEMENTS. Altho satisfactory pavements have been constructed using unheated mineral aggregates and suitable bituminous cements, service tests demonstrate that the best results are secured by using for the mineral aggregate broken stone which is heated until thoroly dry to between 66° C (150° F) and 121° C (250° F). If revolving driers in which the flame is permitted to come in contact with the aggregate are used, great care should be taken to insure uniformity of heating and so avoid the danger of burning the aggregate. In order to obtain a fluidity of the bituminous material which will be sufficient to ensure a proper coating of the mineral particles in cases where a heated aggregate is used, and also to prevent injury to the bituminous material, the asphalt cements should be heated to a temperature between 135° C (275° F) and 177° C (350° F), and refined tars to a temperature between 93° C (200° F) and 135° C (275° F).

"Mixing. The quantity of bituminous cement to be used in the mix will depend on the kind of broken stone or gravel and bituminous cement, the character of the aggregate, the climatic conditions, etc. For the aggregate heretofore mentioned (see Art. 5), the bituminous concrete mixture should contain between 5 and 8% by weight of bitumen. The bituminous concrete should be mixed in mixers designed and operated so as to produce and discharge a thoroly coated and uniform mixture of non-segregated aggregate and bituminous cement. Except on small contracts and for repair work, mixers which provide for the heating of the aggregate by the use of a flame in the mixing chamber should not be used, on account of the danger of burning the aggregate or the bituminous cement.

"Laying. To ensure ease of manipulation and the proper compaction of the bituminous concrete, the mixture as delivered on the roadway should have a temperature of not less than 66° C (150° F). Experience has demonstrated that a thickness, after rolling, of 2 in of bituminous concrete is economical and efficacious. In order to secure an even surface and adequate compaction by a thoro interlocking of the particles of the aggregate, a tandem roller weighing between 10 and 12 tons should be used.

"Seal Coat. A seal coat should always be used on this type of bituminous concrete, as maintenance charges and annual cost will be reduced materially thereby. The seal coat should consist of from ½ to 1 gal per sq yd of bituminous cement, uniformly distributed, preferably by the use of a hand-drawn distributor followed by a squeegee. The bituminous cement should be covered with an application of dry stone chips, which should be rolled.

"Seasonal Limitations. Bituminous concrete of this type should not be mixed or laid when the air temperature in the shade is lower than 10° C (50° F), as otherwise it will be difficult, under average conditions, to secure an even and well compacted wearing course."

Details of Construction of the Ashokan, N. Y., Bituminous Concrete Pavement on part of the 32-mile contract for a highway around the Ashokan Reservoir of the Board of Water Supply of New York City are described as follows (20):

"The bituminous concrete was mixed so that the resulting mixture contained, by weight, 6.25% of asphaltic cement, the stone ranging in size from ¼ to 1¼ in. The temperature of the stone, after drying and heating, was fixed at a maximum of 107° C (225° F), and the asphalt ranged from 135° to 149° C (275° to 300° F), as it was found that these temperatures reduced the draining from the wagons to a minimum.

"The resulting mixture was hauled to the place of laying in bottom dump wagons. The mixture, temperature not less than 66° C (150° F), was dumped onto platforms consisting of planks placed loosely side by side, a few feet in advance of laying. From here it was shoveled into place and spread with rakes to the requisite thickness for rolling with an 8-ton tandem roller to a compacted thickness of 2 in. It was found that the compression due to rolling was generally ⅝ to ¾ in. The amount of asphaltic cement, including seal coat, averaged 19.2 lb or 2.3 gal per sq yd of road surfaced. A single plant, Cummer, laid as much as 1500 sq yd of 2 in bituminous surfacing in one day, but 700 to 800 sq yd, omitting delays, was about the average.

"After rolling, a seal coat, not to exceed 1 gal per sq yd, was spread and covered with stone chips. The dry stone chips were spread in two operations. The first spreading was very light and the rolling resulted in forcing the chips into the seal coat between the interstices of the coated stones of the wearing surface. After a thoro rolling a more liberal coating of stone chips was spread and rolled. The surface was then ready for traffic.

"For purposes of operating, the roads to be surfaced with bituminous pavement under this contract were divided into four groups. On roads of Group A, the plant the contractor had in effective operation consisted of from one to four, mostly three, stone outfits and one asphalt outfit. On these roads (during 1914) 51 700 lin ft of 6-in foundation courses, 14 ft wide, were laid, and 88 000 sq yd of 2-in bituminous surface and seal coat. Effective progress was made on 155 days out of a total of 170 days for foundation courses, and 98 days for bituminous surfacing out of a total of 160 days, so that the total daily average rate for foundation courses was 304 lin ft, and 550 sq yd for bituminous surface."

Construction of Class A Pavements Composed of Two or More Layers of Bituminous Concrete. The use of this type of bituminous concrete

pavement since 1900 has been mostly confined to Great Britain. The aggregates have been mainly granite and slag, the use of the latter largely predominating. The excellent tar slag concrete pavements known as Tarmac, which have been laid in England since 1903, are of this type. Altho laid by various municipalities, the largest yardage of this type has been constructed by Tarmac, Ltd. One of the Tarmac plants is located at Wolverhampton, adjacent to the works of a company producing large quantities of blast-furnace slag. The large molds of slag are transported by small cars from the iron works on a narrow gauge track and dumped near the Tarmac plant. These large blocks, while still warm, are broken by sledge-hammers to sizes suitable for the crusher. After it is crushed and screened into sizes varying from ¼ to 2½ in, it is mixed with a tar compound. Since the slag is warm, even after it has been crushed, no heating, preliminary to mixing, is necessary.

Altho in some cases two courses of tar slag concrete are used, usually more than two layers of tar-coated slag are employed. The principal features of the construction of three-layer tar slag concrete pavements are covered by the following description of a Tarmac pavement laid at Brighton-on-Sea, England. On a well-compacted gravel foundation there was spread a scattering of tar-coated slag chips; the bottom layer was composed of 2½ in of compacted 1¼ to 2½-in tar-coated slag; the second course consisted of 2 in of compacted ½ to 1½-in tar-coated slag; the third course was composed of a thin layer of ⅛ to ⅜-in tar-coated slag chips, which layer was thoroly rolled; the pavement was finished by rolling a top dressing of uncoated fine slag screenings.

Directions for Laying Tarmac by E. Purnell Hooley, County Engineer of Nottingham, Eng. "Before the applying of any Tarmac, the surface of the road that will be left in the center must be carefully swept, and all dirt, dust or loose material removed. The ⅝-in gauge material will always arrive first, and should this not happen, notice must at once be given to the County Surveyor. The ⅝-in must then be lightly spread as a fine bottom layer to fill up any unevenness, to prevent water rising from the under side, and to minimize crushing. The ⅝-in should only be spread about a yard in width at a time, so as to prevent its being trodden upon by the workmen when spreading. On this ⅝-in must immediately be laid a layer of 2¼-in gauge Tarmac, each piece being packed as close to its neighbor as possible. Generally the passage over of the roller about four times each way is sufficient to consolidate this first 2¼-in layer, and the roller must at all times roll the sides towards the center. When the surface is thus rolled, a small dressing of ⅝-in gauge Tarmac must be carefully swept with a dapping motion of the brush into every interstice, and not again rolled until an application of 1½-in Tarmac shall have been applied. The roller then shall pass over this 1½-in gauge material about three times each way, rolling from the sides to the center. A sufficient quantity of ⅝-in material shall again be applied to fill up the interstices, and the roller passed over to place this filling in position. On the completion of the whole, a dressing of fine dry slag dust shall be swept over the surface. After the first rain has soaked the slag dust, the workmen shall immediately sweep the whole road from the center to the sides to remove any surplus dust from the Tarmac, and use as much as possible of this surplus dust on the dry sides, if necessary, or remove it entirely from the surface to the nearest depot. Each 7 sq yd of finished Tarmac road should contain approximately 1 ton. Each 100 ton of material, if laid by this system, should consist of: 3 ton of ⅜-in dry slag; 12 ton of ⅝-in Tarmac; 40 ton of 1½-in Tarmac; 45 ton of 2¼-in Tarmac."

13. Specifications for Class A Pavements

Mineral Aggregate Composed of One Product of a Stone Crushing and Screening Plant. Am. Soc. Mun. Imp. 1917 Specifications. For specifications for the mineral aggregate, see Art. 8. For specifications for the bituminous cements, see Art. 10.

"**General Description.** The bituminous concrete wearing course shall consist of a compact mixture of broken stone and asphalt cement or refined tar laid to conform to the required grades and cross-sections, covered with a seal coat of asphalt cement and broken stone chips, and constructed as hereinafter specified.

"**Heating Mineral Aggregate.** Before entering the mixer, the broken stone for the mineral aggregate shall be heated until thoroly dry to between 66° C (150° F) and 121° C (250° F), as directed, in revolving driers in which no flame shall be permitted to come in contact with the broken stone and in which the broken stone shall be continuously agitated during the heating.

"**Heating Bituminous Cement.** The asphalt cement or refined tar shall be heated in kettles so designed as to admit of even heating of the entire mass, with an efficient and positive control of the heat at all times. Asphalt cement shall be heated as directed to a temperature between 135° C (275° F) and 177° C (350° F). All asphalt cement heated beyond 177° C (350° F), either before or during mixing with the broken stone, shall be rejected. Refined tar shall be heated as directed to a temperature between 93° C (200° F) and 135° C (275° F). All tar heated beyond 135° C (275° F), either before or during mixing with broken stone, shall be rejected. No tar shall be heated in kettles containing any asphalt cement and in like manner no asphalt cement shall be heated in kettles containing any tar. Before changing from one type of material to the other, kettles shall be scrupulously cleaned in order to avoid mixtures of the two. Any such mixtures resulting from this cause shall be rejected.

"**Thermometers Furnished by Contractor.** The contractor shall provide a sufficient number of accurate, efficient, stationary thermometers for determining the temperature of the asphalt cement or refined tar in kettles.

"**Mixing.** When thoroly heated to the temperature directed, the asphalt cement or refined tar and the broken stone for the bituminous concrete shall be mixed so that the resulting mixture shall contain between 5 and 8% by weight of bitumen, as directed, depending primarily upon the kind of bituminous cement and mineral aggregate which are used. A mixer shall be used, having revolving blades, and so designed and operated as to produce and discharge a thoroly coated and uniform mixture of non-segregated broken stone and bituminous cement. When discharged, mixtures of asphalt cement and broken stone shall have a temperature not more than 149° C (300° F) and not less than 93° C (200° F) as directed. When discharged, mixtures of refined tar and broken stone shall have a temperature not more than 121° C (250° F) and not less than 66° C (150° F).

"**Surface of Foundation.** Before laying the bituminous concrete, the surface of the cement-concrete foundation shall be dry and thoroly cleaned. If any defective areas exist in the cement-concrete foundation, they shall be repaired as directed at least 10 days in advance of laying the bituminous concrete. In cases where cement-concrete edging is not used, compacted shoulders, forming a continuation of the surface of the foundation, shall be constructed. A 2-in plank shall be laid on each shoulder at the edge of the foundation. These planks shall remain in place until after the seal coat has been finished.

"**Prevention of Dust.** The shoulders of the road and adjacent grounds shall be sufficient sprinkled during the placing of bituminous material wherever there would otherwise be danger of clouds of dust blowing over the pavement.

"**Laying Bituminous Concrete.** The bituminous concrete, heated and prepared as specified, shall be delivered direct from the mixer to the point of deposition on the foundation in trucks or wagons, provided with canvas covers for retaining the heat. As delivered the bituminous concrete shall have a temperature of at least 66° C (150° F). Material having a lower temperature than this shall not be laid upon the foundation. The hot bituminous concrete shall be dumped upon platforms, constructed as directed, and shoveled with hot shovels into position on the foundation. The bituminous concrete shall be immediately uniformly spread over the foundation course by men experienced in such work and thoroly compacted by rolling. When compacted the wearing course shall have a thickness at no place of less than 2 in and shall be free from surface depressions and irregularities. The paving shall be done as continuously as practicable, to reduce to a minimum the number of joints between hot and cold materials. Such joints shall be constructed as directed.

"**Rolling.** The bituminous concrete wearing course, laid as specified above, shall be rolled at once, while the mixture is warm and pliable, beginning at the edges and

working toward the center. Means for preventing the bituminous material from adhering to the roller without injury to the bituminous concrete, shall be provided. Rolling shall continue without interruption until all roller marks disappear and the surface shows no further compressibility. Places which the roller cannot effectively reach shall be compacted with hot iron tampers.

" **Roller.** Rollers used on the bituminous concrete shall be well balanced, self-propelled, tandem rollers, weighing between 10 and 12 tons each. Each shall have a compression under the rear roller of between 250 and 350 lb per lin in of roll, and shall be provided with an ash pan, which shall prevent ashes from dropping onto the bituminous concrete or seal coat.

" **Testing.** Before placing the seal coat, the surface of the bituminous concrete shall be tested with a 4-ft straight edge laid longitudinally upon any portion of the surface, and any depression or other irregularity exceeding $\frac{3}{8}$ in shall be satisfactorily eliminated.

" **Seal Coat.** As soon as possible after the compaction of the bituminous concrete, when the surface is clean and dry, a seal coat of the hot asphalt cement shall be evenly distributed over the bituminous concrete and uniformly spread by means of squeegees. The asphalt cement shall be applied at a temperature not less than 135° C (275° F), nor more than 177° C (350° F), at a rate of $\frac{1}{2}$ to 1 gal per sq yd, as directed. A thin, uniform layer of dry, clean broken stone chips shall be immediately uniformly spread in two applications over the asphalt cement by machines or skilled workmen. Each application of broken stone chips shall be rolled twice by a self-propelled, tandem roller. The spreading of the broken store chips shall not lag more than 20 ft behind the placing of the asphalt cement coating. Broken stone chips shall not be placed on the wearing course before the asphalt cement of the seal coat is applied. The surface of the bituminous concrete shall be kept scrupulously clean until the seal coat is applied, and the contractor shall not permit any hauling over the wearing course before the completion of the seal coat.

" **Broken Stone Chips.** Broken stone chips shall consist of the product of a stone crushing plant obtained by passing the broken stone thru a section of a rotary screen having circular openings $\frac{3}{8}$ or $\frac{1}{2}$ in in diameter and over a screen having openings of $\frac{1}{8}$ or $\frac{1}{4}$ in.

" **Seasonal and Weather Limitations.** No bituminous concrete shall be mixed or placed when the air temperature in the shade is below 10° C (50° F).

" **Measurement and Payment.** The quantity of bituminous concrete wearing course to be paid for under this item shall be the number of square yards, measured horizontally, satisfactorily completed in accordance with the specifications. The price stipulated in this item shall include the furnishing, crushing and screening of the broken stone, including the broken stone chips for the seal coat, and heating, mixing, placing and rolling of the broken stone and the asphalt cement or refined tar, and all work and expenses incidental to the completion of the bituminous concrete and the seal coat, except the furnishing of the bituminous cement, which will be included for payment under the item Asphalt Cements and Refined Tars for Wearing Course of Bituminous Concrete Pavement or the items Asphalt Cements and Refined Tars for Wearing Course of Bituminous Concrete Pavement and Asphalt Cements for Seal Coat for Bituminous Concrete Pavement. Measurement under this item shall not include any pavement repaired or relaid, except as provided for in the following paragraph.

" **Removing and Replacing Wearing Course.** If the contractor removes, as directed, portions of the wearing course, and the work thus exposed for examination is found satisfactory, or if for any reason he shall be ordered to remove wearing course built in full accordance with his contract, he shall be paid for such excavation one-fourth the price per square yard stipulated in this item. If the wearing course after examination is found to be of acceptable quality, the original wearing course will be paid for as well as that used to refill the excavation. In connection with the removing and replacing of the wearing course in accordance with this paragraph, no quantity shall be measured as less than 1 sq yd."

Road Board of England Specifications for Bituminous Concrete Pavement Having a Mineral Aggregate Composed of Broken Stone or Slag.

" **Foundation.** Any road which is to be surfaced with tar macadam (Class A tar concrete) should have a proper foundation or sub-crust of adequate thickness to bear the traffic likely to use it. Before laying a new surface of tar macadam the thickness of

the old crust, including foundation, should be ascertained by opening trial trenches at intervals averaging about 150 yd extending from the haunch of the road to the center, such trenches to be made alternately on opposite sides of the road.

"The Thickness of the Surface Coating of tar macadam when consolidated by rolling should be from 2 to 3 in, according to traffic requirements. For a greater thickness than 3 in the material should be applied in two coats. In the case of naturally hard sub-soils, not materially softened by infiltration of surface water, the total thickness of the road crust, including foundation, if any, after consolidation of the new surface of tar macadam by rolling, should not under ordinary circumstances be less than 6 in, unless the sub-soil is so hard as in itself to act as a good foundation, in which case the thickness of the road crust may be reduced to 4 in. In the case of clay or other yielding sub-soils the total thickness should not be less than 11 in.

"Cross-Section. The finished surface should have a cross-fall of about 1 in 32. If the crust is not sufficiently thick at the crown to enable this cross-fall to be obtained with a new coating of the thickness above mentioned, then the old surface should be left intact and unscarified, and the thickness of the new coat of tar macadam increased as far as may be necessary. If the crust is of sufficient thickness for the purpose, the regulation of the cross-fall should be carried out by scarifying the surface and removing material from the crown to the sides previous to the application of the new coating. The material loosened by scarifying should be screened and all finer material than ½ in should be thrown aside.

"The Aggregate of the new surface of tar macadam should be composed of broken stone of approved quality, or selected slag of approved quality, and should contain at least 60% broken to the size of 2½ in, not more than 30% of from 2½ to 1¼ in, and 10% of ¾ to ½ in for closing. The last-mentioned size should be kept separate and used as top dressing during rolling operations. The stone used must be thoroly dried before being coated with tar.

"Tar Cement. For making tar macadam, tar should be used which complies with Road Board Specification Tar No. 1, or Road Board Specification Tar No. 2 (see Sect. 14, Art. 5), the choice being determined by the circumstances of each case. If tar No. 1 has been used for tarring the stone, care should be taken, especially in hot weather, that the tarred material has been allowed to stand for a sufficient length of time to allow the tarred surface of the stones to become partially hardened and in a tacky condition. If tar No. 2 has been used for tarring the stone, the macadam should be laid soon after being tarred, and if the tar be of the heavier grade of this quality the stone coated with such tar should only be laid when the road is quite dry and in warm sunny weather. The quantity of tar used, to coat 1 ton of stone, should be approximately from 9 to 12 gal, varying according to the sizes of the stone, the grade of tar used, the method of mixing and other conditions.

"Laying and Rolling. The tar macadam, after having been spread and levelled, should be rolled into a smooth surface, but too much rolling should be avoided. Less rolling is required than in the case of water-bound macadam. A 10-ton roller is a suitable size for use in most cases, but good results can be obtained by using a 6-ton roller and finishing with a 10-ton roller.

"Seal Coat. In order to get the best results from the use of tar macadam, it is advisable to apply a coating of tar to the surface after the road has been used by traffic for several weeks. This tar should comply with the provisions of Road Board Specification for Tar No. 2, and should be poured or sprayed on the surface at a temperature of about 132° C (270° F). Stone chippings, crushed gravel, coarse sand or other approved material, free from dust, not larger than will pass thru a ¼-in sq mesh, should be used for gritting in quantity not exceeding 1 ton for 300 to 350 superficial yd, if grit is used, and 1 ton for 200 to 250 superficial yd if coarse sand is used."

Tarmac Pavement Specifications, as used in some districts in England, are as follows:

The Crossfall for Tarmac pavements shall be 1 in 32, or about ⅜ in to 1 ft.

Laying. "The Tarmac shall be applied in two layers, the bottom layer consisting of 2¼-in gauge, the top layer of 1½-in gauge. Each layer shall be separately consolidated with a roller of about 8 to 10 tons in weight. The surface of the top layer consolidation should be well sprinkled with ⅝-in material, so as to fill all interstices, and again rolled to complete consolidation and an even and water-tight surface, being

afterwards blinded with slag or other suitable grit at the rate of 1 ton to every 250 sq yd of road surface. The thickness of each coat, for a total thickness of 3 in, shall be 2 in for the bottom coat and 1 in for the top coat; the proportions of gauges required being 5 of 2¼-in, 4 of 1½-in, and 1 of ⅜-in.

Maintenance. "It is recommended that, generally speaking, once during the first 12 months after completion, the roadway shall be swept clean of all surface matter, and painted with refined tar at the rate of about 7 sq yd to 1 gal, and blinded with suitable slag or other chippings ⅜-in down to dust, at the rate of 1 ton to every 200 yd of surface. This painting should again be carried out during the third year after completion."

14. Construction of Class B Pavements

The methods of mixing and laying Class B bituminous concretes are similar to those described and discussed as applicable to Class A bituminous concretes, except that hand mixing methods should never be employed. The mixing and laying of combinations of broken stone, sand and filler, or similar materials, must be carried on with exceptional care in order to prevent the segregation of the different sizes of the aggregate. The plants employed include all the machines described in Art. 11. To secure the best results, the plant should have a rotary drier, a pug-mill mixer, and, preferably, storage bins and weighing devices. For details of operation of portable, semi-portable and stationary plants, see Art. 11 and Sect. 17, Arts. 13 and 14. Methods of laying are discussed in examples of construction given in this Article, in Art. 12, and in Sect. 17, Art. 15, and are described in detail in the specifications cited in Art. 15. For methods of constructing AMIESITE and FILBERTINE pavements, see Art. 15.

Construction of Class B Pavements in Washington, D. C. by Brooke (23b). For description of mineral aggregates used, see Art. 6.

"The paving mixture is prepared in a sheet-asphalt paving plant. The sand and stone after being heated in separate driers to about 149° C (300° F), are conveyed to the box used for mixing binder stone where the hot asphaltic cement and cold limestone dust are added and the whole thoroly mixed. The method of laying is described in the specifications as follows: The mixture will be hauled while hot to the site of the work and shall be covered until deposited on the street. The temperature at the time of dumping shall not be less than 104° C (220° F). The hot mixture shall be evenly spread with hot tools upon the base to such a thickness as will make a layer 2 in in thickness after rolling. It shall then be rolled with a steam roller, weighing not less than 1 ton per ft of tread of roller until no further compression occurs. After the rolling of the asphaltic concrete wearing surface has been completed, there shall be spread over such surface a thin coating of asphaltic cement, as used in the surface, not to exceed on an average ¼ gal to the sq yd, of such consistency as shall be approved, which shall be thoroly brushed into the wearing surface so as to fill all voids and smooth out any minor unevenness of the said surface. There shall be spread over and rolled into this flush coat a thin layer of trap screenings, so far as practicable devoid of dust, in size from ⅜-in down, to secure a gritty, non-slippery surface.

"The asphaltic concrete, particularly if there is a slight excess of cement, tends to separate during the haul to the street, the fine material and cement working to the bottom of the wagon. In cold weather it is essential that the material arrive on the street amply hot, as the slightest chill stiffens it and makes it very difficult to spread and roll. For these reasons, aside from other considerations, motor trucks have been found to be better than carts or wagons for the hot haul.

"Some difficulty has been experienced in applying the flush coat in sufficient quantity to seal the surface without causing the formation of a mat which would cover up the stone aggregate and produce a slippery surface. The specification originally provided for the application of a thin coat of hot asphalt cement. On several streets the hot cement used in the paving mixture was tried. On one street this surface was so objectionable that it has been necessary to sand it each summer. The effect of the coarse sand and the partial wearing off of the mat and consequent exposure of the stone are

gradually curing this slipperiness. After this experience the hot application was abandoned for an asphaltic emulsion which is applied cold, broomed in, and then covered with chips. After the evaporation of the water and emulsifier, ammonia, a light coating of asphalt is left. This method gives the rough mosaic surface which is desired but it is questionable if there is sufficient body of cement to bind the fine material and effectually seal the surface. It is believed it would be practicable to obtain a satisfactory flush coat by applying a lighter cement with a power distributor, such as used in macadam surface and penetration work, and the engineer department intends to try this method.

"The average price of this pavement laid to a thickness of 2 in after compression, including a 6-in gravel concrete base and grading for same, has been \$1.79, which includes a 5-year guarantee. The average price for the pavement without base has been \$0.97, including guarantee. The average cost of macadam base has been \$0.345, making cost of bituminous concrete pavement on macadam base, \$1.31."

Details of Construction of Class B Bituminous Gravel Concrete Pavement, built in 1916 on the Alexandria-Accotink Road, Fairfax County, Va., under the direction of the U. S. O. P. R. (67d). The pavement is 24 500 ft long and has an area of 38 443 sq yd. For details of construction cost data, see Art. 21.

The Aggregate consisted of crushed and screened gravel; coarse aggregate passed 1¼-in and was retained on ¼-in circular openings; fine aggregate passed ¼-in circular openings, and contained less than 5% of clay; ordinary ground limestone was used as a filler; washed Potomac River gravel, screened thru ½-in and over ¼-in screen was used as top dressing for seal coat.

Mixing. The mixing plant was of the stationary type, operated by steam power. The gravel was excavated by hand, run thru a jaw crusher, and screened to remove tailings before it was heated. The heating was done in two rotary drums, wood being used as fuel. The fine and coarse aggregates then were separated by means of a ¼-in screen and stored in two bins immediately over the mixer. The asphalt cement, having a penetration of 64 at 25° C (77° F), was heated in two kettles supplied with steam coils, and the mixing was done in an ordinary twin pug mixer. The average time for mixing a batch was 1 min. Analysis of 61 plant samples of mix gave the following averages: Bitumen, 6.5%; aggregate retained on ¼-in screen, 54.5%; aggregate passing ¼-in screen and retained on a 200-mesh sieve, 35.8%; aggregate passing 200-mesh sieve, 3.2%.

Laying. The hot mix was dumped from the trucks or wagons onto a steel dumping board and spread with hand shovels and asphalt rakes. Then it was set by rolling with a 2½-ton tandem roller and compacted to its final shape with an 8-ton tandem roller. The loose depth of the hot mix averaged about 2¾-in, and the compacted depth was not less than 2 in. The temperature at which the material was spread ranged from 93° to 149° C (200° to 300° F).

The Seal Coat was of the same asphalt used in the mix, covered with pea gravel. The asphalt was spread at a temperature of about 177° C (350° F), about ⅛ gal per sq yd being used. The pea gravel was spread at the rate of about 1 cu yd to 150 sq yd of surface. After the gravel was spread the surface was rolled with the 8-ton tandem roller.

15. Specifications for Class B Pavements

Mineral Aggregate of Broken Stone or Gravel, Sand and Filler. Ill. State Highway Dept. 1917 Specifications, in abstract.

"Tests for Broken Stone. The crushed stone shall be hard and sound and shall have a coefficient of wear according to the Duval test of not less than 8 when used for the second course, and of not less than 6 when used for the lower course only. If the cementation value of the stone is less than 25, a good bonding gravel or other material satisfactory to the engineer shall be used as a binder for the lower course of stone. Slag or similar material may be used subject to the approval of the engineer. All tests shall be made in accordance with the methods outlined in Bul. 44 of the U. S. O. P. R., Washington, D. C.

"The Size of Crushed Stone that shall be used is as follows: Broken to a size that will pass over a ½-in ring and will just pass thru a 1½-in ring, which size will hereinafter be referred to as 1½-in stone. Not less than 30% nor more than 80%

of this stone shall be retained on a ¾-in ring. This stone shall be clean and entirely free from dust.

"Gravel may be used instead of the size of stone designated above providing it complies with the following requirements for the respective sizes and consists of hard materials meeting the approval of the engineer: Ranging from a size that will pass thru a 1½-in ring and will pass over a ⅝-in ring, which size will hereinafter be referred to as 1½-in gravel. Not less than 25% nor more than 75% shall be retained on a ¾-in ring and at least 30% of the gravel shall be crushed material. Gravel deficient in crushed material may be used mixed with crushed stone when approved by the engineer. All 1½-in gravel shall be entirely free of dust, clay, loam or organic matter.

"The following size of gravel shall be used on all contracts: Ranging from a size that will pass thru a ⅝-in ring and graded to fine sand, which size will hereinafter be referred to as grit sand. Not less than 40% nor more than 80% of the grit sand shall pass thru a 20-mesh sieve. It shall consist of hard grains and shall not contain more than 2%, by dry weight, of clay or organic matter.

"**The Filler** used in the bituminous concrete shall be a Portland cement, limestone, or silica ground to a fine dust, at least 75% of which will pass a 200-mesh sieve, and at least 95% of which will pass a 50-mesh sieve.

"**The Second Course** shall consist of 1½-in stone, grit sand and filler which have been mixed with the bituminous material in a suitable power mixer at the temperature prescribed by the engineer.

"**Bituminous Aggregate.** In order to obtain a dense concrete, the 1½-in stone, grit sand, filler and bituminous binder shall be used in the proportions required by the engineer, but unless otherwise instructed, the contractor shall mix the stone and the grit sand in the ratio of 2½ cu yd of stone to 1 cu yd of sand, and they shall be thoroly mixed with 150 lb of filler per cu yd of stone, and not less than 30 nor more than 33 gal of the bituminous material per cu yd of stone. Should the bituminous binder meeting the requirements of specifications A contain less than 95% of bitumen, then enough binder shall be used to furnish not less than 30 nor more than 33 gal of the bitumen per cu yd of stone, and the quantity of filler used shall be decreased to the amount required by the engineer. The engineer shall be permitted to take samples of the bituminous aggregate at any time to determine if the materials have been mixed in the required proportions.

"**Seal Coat.** After rolling, a seal coat of ⅓ to ½ gal of the bituminous binder shall be applied at the temperature prescribed by the engineer. It shall be covered immediately with just enough grit sand to prevent it from sticking to wheels, and then rolled. The road shall be allowed to stand for at least ½ day before being opened to traffic."

Mineral Aggregate of Broken Stone, Slag or Gravel and Filler. W. Va. State Road Comm. 1917 Specifications, in abstract.

"**Aggregates.** The fine and coarse aggregates shall consist of approved stone, slag, or gravel passed thru a stone crusher and crushed so that all particles will pass a screen having circular openings 1¼ in in diameter. The product of the crusher shall be passed over a screen having circular openings ¼ in in diameter and that part of the product which passes this screen is designated fine aggregate, while that part of the product which fails to pass a ¼-in screen is called coarse aggregate. The coarse aggregates shall not contain an appreciable amount of clay, loam, or soil, and the fine aggregate shall not contain more than 5% by weight of such material.

"**Filler.** The filler shall consist of limestone dust or Portland cement, and shall be of such fineness that all will pass a 30-mesh sieve and not less than 66% will pass a 200-mesh sieve.

"**Mixing.** The bituminous concrete shall consist of from 40 to 60% by weight of coarse aggregate, from 30 to 45% by weight, of fine aggregate, from 3 to 5%, by weight, of filler, and from 6 to 8%, by weight, of bituminous material, the exact percentages of each to be furnished by the engineer from time to time as the work progresses. The fine and coarse aggregate may be mixed together in approximately designated proportions, and shall be heated in a rotary drier to a temperature of 149° to 177° C (300° to 350° F), and when still hot shall be separated into sizes designated for fine and coarse aggregates, the fine aggregate and coarse aggregate passing into separate bins. From these bins and before the aggregates have materially cooled,

the required amount of each aggregate for a batch shall be dropped into an approved mixer. The required amounts of filler and hot bituminous material shall then be added, and the whole thoroly mixed until all particles of the aggregate are coated with the bituminous material."

Amiesite Pavement: Penn. State Highway Dept. 1917 Specifications.

"**Asphalt.** The asphalt used in this type of pavement shall conform to the following specifications: Specific gravity not less than 1.00; solubility in carbon disulphide not less than 99%; penetration at 25° C (77° F), 100 g, 5 sec, Dow method, not greater than 175 and not less than 125, and after heating 5 hr at 163° C (325° F), a 50-g sample shall show a penetration at 25° C (77° F), 100 g, 5 sec, Dow method, not less than 50% of the original penetration; the ductility at 50 penetration shall be not less than 50 cm.

"**Mineral Aggregate.** Mineral aggregate for the bottom course shall be clean, crushed rock of approved quality run of crusher passing a 2-in screen and being retained on a ¼-in screen, free from foreign materials. The French coefficient of wear shall be not less than 12. Mineral aggregate for the top course shall be similar, except that all of it shall pass a ⅝-in screen and be retained on a ¼-in screen.

"**Filler.** The filler shall be clean, crushed rock screenings of approved quality, all passing a ¼-in screen.

"**Mixing.** The mineral aggregate shall be treated with a liquefier to make the asphalt adhere. The asphalt heated to approximately 135° C (275° F) then shall be added and after the mineral aggregate is coated thoroly, ground oxide or hydrate of lime shall be added. The ingredients referred to above shall be mixed in the following proportions:

	Bottom Course	Top Course
Mineral aggregate	86 to 90%	86 to 90%
Filler	4 to 6%	5 to 8%
Asphalt	5 to 6%	5 to 7%
Lime	½ to 1%	½ to 1%
Liquifier	½ to 1%	½ to 1%

"**Unloading Surface Mixtures.** When necessary, the Amiesite may be steamed to facilitate its unloading from cars. Steam pressure shall not exceed 15 lb to the sq in and the Amiesite shall not be steamed more than 15 min in any one place. This work shall be done under the supervision of the inspector in charge.

"**Delivery of Surface Mixtures.** Amiesite surfacing materials shall be delivered upon the work in tight vehicles, cleaned previously of all foreign materials. The surfacing materials shall be unloaded from the wagons upon iron sheets or boards at such distance from the point of spreading that all the mixture will be turned completely in distributing it to place. The dispatching of vehicles shall be arranged so that all material delivered may be placed and shall have received initial rolling in daylight.

"**Placing Wearing Surface.** The bottom course shall be spread in a uniform layer of not less than 2¼ in in depth when measured loose, using blocks or strips to insure an even distribution, and then rolled thoroly. If any depressions appear they shall be filled with Amiesite and rolled until the surface is even and to the grade desired. After this preliminary rolling the top course shall be applied, not less than 1 in in depth, loose measurement, and raked to an even depth so as to cover the underlying bottom course and fill the voids. The bottom course in no case shall be spread more than 300 ft in advance of the top course, nor more than 50 ft of the bottom course shall be left uncovered during the night. The total compressed depth of finished Amiesite surface shall be not less than 2 in.

"**Conditions for Placing.** No Amiesite shall be spread when the road-bed contains depressions holding water. The Amiesite shall be kept clean at all times. Dirt or other foreign material shall not be allowed to mix with, under, or on the Amiesite while being unloaded from cars, spread and rolled. Should the bottom course become

coated or partly coated with dust or dirt before the top course can be applied, the part thus coated shall be swept and then given a light application of bituminous cement that can be applied from a sprinkling pot so constructed that a thin and uniform application can be made easily.

" **Rolling.** After the top course has been spread evenly to grade, the surface shall be rolled with a power roller of at least 8 tons weight until the material is compacted thoroly and ceases to creep in front of the roller. The rolling shall start from the side lines of the street or road and work toward the center. Care shall be taken that the shoulders are firm and solid, as otherwise the surface mixture will iron out to a feather edge and crack. No rolling shall be done unless the Amiesite is free from water. The road shall be rolled also diagonally and transversely, the amount of these rollings equalling the longitudinal rolling.

" **Surface Finish.** After this rolling is finished, approved, clean, dry sand or approved fine stone screenings passing a ¼-in screen shall be spread in a thin layer and rolled. The road then may be thrown open to traffic. The finished surface shall conform with the grade and cross-sections given."

Filbertine Pavement: Penn. State Highway Dept. 1917 Specifications.

"**Asphaltic Cement.** The asphaltic cement shall be known as R. Y. Filbert's Improved Waterproof Filbertine Paving Cement and shall comply with paragraphs 158 and 159. The penetration of the asphaltic cement 100 g, 5 sec, 25° C (77° F), shall be 50 to 65, as directed.

" **Composition and Preparation of Mixture.** The mineral aggregate in the Filbertine mixture shall be composed of sound, hard, crushed trap rock, having a French coefficient of wear of not less than 12, or other approved stone having a French coefficient of wear of not less than 10; sand such as required for asphaltic wearing surface mixture, paragraph 160; and stone dust or Portland cement, which shall be combined with the asphaltic cement within the following proportions best suited for making a dense mixture:

Bitumen	6 to 8%
Filler, stone dust, or Portland cement	4 to 6%
Stone, ¾-in hard crushed	55 to 60%
Sand	30 to 35%
Other ingredients	not more than 1%

" **Delivery of Surface Mixture.** Filbertine mixture shall be delivered upon the work in tight vehicles previously cleaned of all foreign materials. The vehicles shall be covered with canvas of sufficient size to protect the entire load and shall be dispatched so that all materials delivered may be placed and shall have received initial compression in dayligh .

" **Placing.** The mixture, on reaching the work, shall be deposited outside of the area on which it is to be spread and then shall be spread on the prepared foundation by suitable means to proper depth, the whole of the mixture being turned completely in distributing to place.

" **Rolling.** Initial compression shall be effected with a tandem power roller, weighing approximately 2½ tons, having a main roll of such width as to give a compression of approximately 125 lb per in width of tread, and final compression shall be effected with a power roller of at least 8 tons weight. The rolling shall include complete transverse and an equal amount of longitudinal rollings and two diagonal rollings approximately at right angles one to the other. Hot iron tampers shall be used where the roller cannot be used. The rolling and tamping shall be continued until the resultant wearing surface is compressed thoroly and is dense, slightly elastic, firm without brittleness, and durable. The wearing surface as thus constructed shall have a depth of not less than 2 in after ultimate compression.

" **Seal Coat.** Immediately after the initial compression and while the surface is still hot, a prepared seal coat shall be applied uniformly and in such a manner as to fill thoroly all the surface voids in the Filbertine mixture and not to leave a coating of more than ¼ in on the surface of the pavement. The seal coat mixture shall consist of finely graded sand, as required for asphaltic wearing surface, paragraph 160, coated with 9.5% to 10.5% of bitumen by weight. Asphaltic cement as previously specified shall be used in the seal coat mixture. The mixing shall be done in a suitable me-

chanical mixer. The seal coat mixture shall be rolled at once and thoroly into the Filbertine mixture so as to form a perfect bond and the finished surface shall be firm and true to crown and cross-sections."

16. Construction of Class C Pavements

The methods of mixing bituminous concretes of Class C vary to a marked degree on account of the radical differences in the characteristics of the mineral aggregates and the products of bituminous concrete which are included in this classification.

Topeka and Bitoslag Pavements. The methods of mixing and laying are similar to those described in Art. 14 as applicable to the construction of Class B pavements. As the maximum size of the mineral aggregate used in the Topeka mixture passes a ½-in screen and the maximum size of the slag aggregate of the Bitoslag bituminous concrete passes a ¼-in screen, and furthermore, as the general composition of the aggregates are somewhat similar, the methods of construction of these pavements may be identical. To secure the best results, the mixing plant should have a rotary drier, a pug-mill mixer, storage bins and weighing devices. In order to readily secure uniform mixtures of bituminous concrete, the plant should have a screen by means of which the aggregate may be separated into fine and coarse aggregates, deposited into two bins and separately weighed. For details of operation of portable, semi-portable and stationary mixing plants, see Art. 11 and Sect. 17, Arts. 13 and 14.

Laying. Methods of laying are discussed in the examples of construction given in this Article, in Art. 12, and in Sect. 17, Art. 15, and are described in detail in the specifications cited in Art. 17.

Seal Coats. Practice varies relative to the use of seal coats on Topeka pavements. The efficiency of seal coats depends mainly upon the kind of aggregate, and the amount and character of the traffic. Based on service tests, it does not appear that Bitoslag pavements, which have a finer aggregate than Topeka, require bituminous seal coats. Generally, it will prove economical to use seal coats on Topeka pavements subjected to horse-drawn commercial traffic as the blows from horses' shoes may dislodge ¼ to ½-in particles of aggregate in the surface of the pavement. In cases where gravel is used for the coarse aggregate, it is always advisable to use a seal coat to prevent the particles of gravel from pitting out. Seal coats on Topeka wearing courses should be thin and uniform in amount. The method of application must be varied to suit the characteristics of different kinds of bituminous cements. For example, a tar cement can readily be applied by hand-drawn gravity or pressure distributors or pouring cans and further distributed by brooms, mops or squeegees, whereas some asphalt cements used with Topeka aggregates would require mixing with a flux before it would be practicable to distribute them in as small an amount as ⅛ to ¼ gal per sq yd. These seal coats are completed by a thin application of coarse sand, fine gravel, or stone chips, which is thoroly rolled. Topeka pavements, which are not finished with a seal coat, and Bitoslag pavements are completed by the application over the thoroly rolled wearing course of a thin dressing of Portland cement or other fine mineral matter. Topeka pavements thus finished have proved satisfactory when subjected to traffic composed mainly of motor vehicles.

Form for Daily Report on Modified Topeka Mixture by Mullen (49b), giving data relative to one sample taken during the construction of the St. Augustin-Quebec Road in the Province of Quebec, Can.

Topeka Tar Concrete Pavements by Sharples (59). "In Pittsburgh, Pa., many streets were laid from 1890 to 1898 under the name of Vulcanite pavement, using coal tar pitch or a mixture of coal tar pitch and asphalt as a bituminous cement. The mineral aggregate varied greatly in different streets but might be said to follow in general the Topeka mix. Lang Ave. is an example of the true Topeka mix and was laid in 1892. The cement used was 49° C (120° F) melting point coal tar pitch, about

30% free carbon, with some small percentage of Trinidad asphalt. The street is residential with a residential street traffic and would be classed as in good condition at the present time (1914), with only nominal repairs during its 22 years of use.

"Much of the early tar concrete work in New England resembles closely Topeka mix with the ½-in crushed stone replaced by pebbles. The following screening analyses of typical New England tar-concrete sands show that sands in Newton and Brighton, Mass., fall within the Topeka specification.

Mineral Aggregate	Topeka	Newton	Brighton
Passing 200-mesh	5 to 11%	4.9%	5.0%
Passing 40-mesh	18 to 30%	24.8%	18.5%
Passing 10-mesh	25 to 55%	55.0%	54.8%
Passing 4-mesh	8 to 22%	12.4%	17.1%
Passing 2-mesh	less than 10%	2.9%	4.6%

"The percentage of tar cement used in New England is usually larger than called for in the Topeka specification. The exact amount is varied to suit the particular sand used, but often runs as high as 12%. It was believed that a large excess provided a reservoir of tar cement which was drawn upon as needed. It would seem from more recent work that a smaller percentage of refined tar in the mix with provision for seal coats as needed would be more economical in the long run. Based upon this principle, work has been done with as little as 6% cement. With this small percentage, it has been definitely proved that a seal-coat protection is a necessity. Eight percent would seem to be a better starting point, and modifications in the percentage should be made to suit local conditions.

"A study of successes and failures in New England tar concrete shows that the requisites for success in using coal tar cement in Topeka mix are:

1. Carefully prepared foundations with due attention to drainage.

2. Suitable sands. Either too fine or too coarse sands are to be avoided. A sharp sand gives better results than rounded grains and a mineral aggregate which has structural strength in itself is to be aimed at.

3. A carefully prepared straight-run coal tar cement with a melting point of 38° to 49° C (100° to 120° F), ½-in cube method in water, varied to suit traffic conditions and local mineral aggregate available.

4. Careful handling of the coal tar cement. Coal tar cement, like other bituminous materials, is easily changed by heating to a high temperature or by holding a long time at a comparatively low temperature, 104° C (220° F), in open kettles. Refined tar, mineral aggregate, and the mix should be kept at or near 104° C (220° F). This point must be especially insisted upon when high melting point materials have previously been used.

5. Expert supervision is just as essential as in all other paving work. The exact method best for local handling, the exact percentage of bitumen required, the correct proportion of mineral aggregate, are matters requiring judgment and experience."

Bitulithic and Warrenite Pavements. The methods of operating Bitulithic and Warrenite plants for the manufacture, respectively, of Bitulithic and Warrenite bituminous concrete mixtures are fully described in Art. 11, and are discussed in Art. 7. Methods of mixing, laying and finishing Bitulithic bituminous concretes are covered in the requirements of the specifications cited in Art. 17, and described in examples of construction given in this Article.

Details of Construction of Bitulithic Pavement in Pierce County, Wash., by White (72). "The pavement has a 2-in Bitulithic top, 16 ft wide, containing 49 878 sq yd, laid on a 5-in 1:3:6 concrete base, with 6-in concrete curbs. The cost to the County was $1.445 per sq yd divided as follows: Subgrade and extras, including curbs, 23.4 cents; concrete base, 60 cents; Bitulithic top, 68.6 cents.

Mixing. "In the construction of this work a one-car asphalt plant was used by changing the sand bin into four compartments. The plant consisted of a rotary drum

to heat the sand and rock, oil being used for fuel, elevators to lift it into the elevated screens and separate it into the different sizes, and the bins into which the sand and rock passed after screening; there were three kettles, heated by coal and staves of the barrels that contained Bitulithic cement, in which the Bitulithic cement was heated, a weighing machine having a scale of seven beams, and weighing platform, buckets and mixing boxes. The crushed rock and sand were separately piled near the end of the rotary drum. A two-horse scraper was used to bring the rock and sand to the elevators where they were shoveled into the elevators which empty into the heating drum. It took about 4 min from the time the aggregate started in the drum to reach the bin. The rock was heated from 116° C (240° F) to 121° C (250° F). After leaving the drum the aggregate was lifted onto the screens which separated it into four sizes, passing into as many bins. No. 1 bin contained aggregate passing 10-mesh; No. 2 bin contained aggregate passing ¼-in screen and retained on 10-mesh; No. 3 bin passing ½-in screen and retained on ¼-in; No. 4 bin passing 1¼-in screen and retained on ½-in. The following proportions were generally used, tho some little variation was made to fit different materials: 315 lb, No. 1 bin; 90 lb, No. 2 bin; 140 lb, No. 3 bin; 440 lb, No. 4 bin; and 15 lb of dust finer than 200-mesh. This made 1000 lb of aggregate, to which was added 88 lb of Bitulithic cement heated to 121° C (250° F). These materials were carefully weighed, passed into a twin pug mill and thoroly mixed for about 1 min 40 sec, and then dumped into a wagon which stood underneath to receive it.

Laying. "It was hauled by teams and dumped onto the street, shoveled over until it was about the thickness required, raked to as smooth a surface as possible. It was then rolled with a 10-ton roller until thoroly smooth and no appreciable compression appeared, and it did not creep under the roller. If any low places developed, a little more material was put on to bring it to the required grade and thickness. After it was rolled, a squeegee car was used to spread the Bitulithic cement, which was heated in kettles on the street, and the top was thoroly coated with the Bitulithic cement, using approximately ¼-gal per sq yd, and then covered with hot screenings from the No. 1 bin with a little excess sand and put on by a sand-spreading machine using approximately 25 lb per sq yd. The pavement was then thoroly rolled with a 10-ton roller.

Organization. "The force required at the plant and the wages paid were as follows:

1 superintendent, furnished by the patentees	$200.00 per month;
1 foreman	100.00 per month;
4 feeders, 3 using shovels and 1 a hoe, to feed the aggregate into the elevators; 1 drum fireman; 1 boiler man; 1 hopper man; 1 mixer man; each	2.50 per day;
1 team	5.00 per day;
1 night watchman	3.00 per day.

From 3 to 13 teams, costing $5 per day, were used to haul the material.

"The street force was as follows:

1 foreman	$4.00 per day;
1 roller man	3.50 per day;
1 man, cleaning pavement	2.25 per day;
1 wagon dumper; 1 tamper; 5 shovelers; 2 rakers; 2 squeegee men; each	2.50 per day.

Warrenite Constructed with Oyster Shell Aggregate (27c). "An interesting example of the use of a bituminous surface, using oyster shell aggregate, may be seen on the Beckwith Neck Road connecting Cambridge and Hillspoint in Dorchester County, Md. The stretch of road improved, located about 1 mile beyond the town of Cambridge, was laid in five continuous sections, each section containing a different mixture, as follows: (1) Whole shells, crushed shells and bitumen; (2) whole shells, crushed shells, sand and bitumen; (3) whole shells, sand and bitumen; (4) crushed shells, sand and bitumen; (5) beach gravel, screened and graded with coarse sand, fine sand and bitumen, a check for use in determining the relative wear. The type of bituminous concrete is known as Warrenite and the surface was mixed and laid by the Warren Brothers Co.

"This surface was laid in the early summer of 1911. When inspected in Oct. 1913, the general condition of the surface was found to be good. In the sections where whole shells were used some of the whole shells which were near the surface with their flat sides up were cracked. The most satisfactory section was the one in which shell, crushed to pass a 1-in ring, sand and bitumen were used."

17. Specifications for Class C Pavements

Topeka Pavement, Am. Soc. Mun. Imp. 1917 Specifications. For specifications for subgrade, drainage and foundations, see Art. 4. For specifications for mineral aggregate, see Art. 8.

" General. On the foundation, as heretofore specified, shall be laid the bituminous concrete wearing surface, which shall consist of a mineral aggregate mixed with bituminous cement and laid as hereinafter specified.

"This wearing surface shall have a thickness of ...... inches after thoro compression with a roller. For heavy traffic a thickness of 2 in is sufficient for all practical purposes and in some cases will afford more stability than a greater thickness. For moderate and light traffic 1½ in will be sufficient thickness for the wearing surface when laid on a well constructed base as specified above.

" Method of Mixing. The aggregate shall be dried and heated in properly designated driers before mixing with the bituminous cement. The driers shall be of the revolving type, thoroly agitating and turning the materials during the process of drying. When the aggregate is thoroly dried and heated to a temperature of from 93° to 177° C (200° to 350° F), depending upon the bituminous cement used, it shall be immediately before cooling or exposure to moisture, mixed with the hot bituminous cement as hereinafter specified. If stone dust is used, it shall be introduced directly into the mixer without passing thru the drier. The bituminous cement shall be melted in a tank arranged so the heat can be properly and easily controlled and regulated. When melted and raised to a temperature of from 93° to 177° C (200° to 350° F), depending on the bituminous cement used, it shall be combined in the proper proportions with the hot aggregate and immediately mixed in a properly designed revolving mixer until a thoro and intimate mixture of the ingredients has been accomplished and the particles composing the aggregate are evenly and thoroly coated with the bituminous cement. The mixer shall not be exposed directly to the action of fire.

" Method of Laying. While still hot from the mixer, the paving mixture shall be spread evenly on the foundation with hot iron rakes and shovels, so that when compressed with the roller it shall have the thickness specified, with the surface even and true to grade. Along the curb and around manholes, catch-basins and other obstructions in the street, where the roller cannot reach, the compression shall be secured by the use of hot iron tampers. The rolling and tamping shall be done as quickly as possible after the material is spread, while still hot and pliable. When the paving mixture is hauled on the street in dump wagons it shall be, when ordered by the engineer, kept covered with canvas to retain heat, dumped on platforms and shoveled into place and raked to the proper grade. As soon as spread the paving mixture shall be rolled with a tandem roller weighing at least 6 tons and the rolling continued, working lengthwise and diagonally of the street. When practicable, additional compression in the wearing surface should be secured by the use of a 10-ton roller. Rolling must be steadily kept up and continued until all roller marks shall disappear and the surface gives indications of no further compressibility.

"The paving shall be done continuously, so the number of joints between the hot and cold material may be reduced to the minimum. When it is not practicable to lay it continuously and a joint is unavoidable, the edge of the cold material shall be trimmed down to a rough feather edge, and the surface, where the joint is to be made, painted over with bituminous cement, the hot material raked over the feathered edge and thoroly rolled. Instead of trimming the cold material, joint strips may be used consisting of strips of canvas about 18 in wide with 3 parallel lines of ¾-in ropes sewed on the under side about 3 in apart. The joint strips shall be laid on the feather edge of the freshly raked material with the upper rope at the line where the thickness begins to decrease and the rolling completed on top of the canvas as for finished pavement. The faces of the curb and gutter, iron castings, etc, shall be painted with bituminous cement before the paving mixture is laid.

" Surface Finish. As soon as possible after the rolling of the mixture is finished, and while the surface is still fresh and clean, and, if possible, while warm, a seal coat of bituminous cement of proper consistency to be flexible when cold shall be spread over the surface. It shall be applied while at a temperature of from 93° to 177° C (200° to 350° F), depending upon the bituminous cement used, and evenly spread with rubber squeegees or mops. Only a sufficient coat shall be spread to flush the

surface voids without leaving an excess. Immediately over this, a top dressing of torpedo sand, fine gravel or stone chips free from dust, which must be thoroly dry and heated in cold weather, shall be spread and thoroly rolled into the surface. A small surplus shall be left to be worn in or worn away by the traffic.

"In the case of park drives and roadways not subjected to heavy, constant traffic, and where a more grainy and coarse surface is desired, the surface finish specified above may be omitted and the following method of finishing adopted: As the bituminous concrete is raked to grade, and just before the roller comes on it, spread dry stone chips or coarse torpedo sand, evenly with swinging motions of a shovel, until the surface is barely covered. Then roll thoroly as specified in the preceding paragraph relating to method of laying. If bare spots appear under the roller, sprinkle more chips or sand and continue the rolling until the whole surface is fairly covered. After the sand or stone chips have worn into the surface the street shall be swept, all excess of surfacing material removed and the street left clean.

"**Asphaltic Cement and Flux.** Use the specifications for asphalt, asphalt cement and flux reported by the sub-committee on sheet-asphalt pavement specifications and adopted by the Society. See Sect. 17, Art. 12.

"**Coal Tar Cement.** The coal tar cement shall be the residue of the distillation of coal tar only, and shall be refined for the special purpose of making a paving cement. No mixture of hard pitch with the lighter oils of coal tar will be permitted.

"Its specific gravity shall be not less than 1.20 nor more than 1.29 at 21° C (69° F).

"The melting point determined by the cube method shall be not less than 38° C (100° F), and not more than 46° C (115° F).

"It shall contain not less than 15%, nor more than 30% of free carbon insoluble in benzol.

"It shall be free from water as determined by distillation and shall show upon ignition not more than 0.5% of inorganic matter.

"No distillate shall be obtained lower than 170° C (338° F), and up to 315° C (600° F) not less than 5% and not more than 20% of distillate shall be obtained. The distillate shall be of a gravity of not less than 1.03 at 15.5° C (60° F). The residue shall have a melting point of not more than 74° C (165° F). In making this distillation an 8-ounce glass retort shall be used and the thermometer suspended so that before applying the heat the bulb of the thermometer is ½ in above the surface of the liquid. The melting point of the pitch shall be determined by suspending a ½-in cube in a beaker of water 1 in above the bottom. The temperature shall be raised 5° per min from 15° C (9° per min from 60° F). The temperature recorded the instant the pitch touches the bottom shall be considered the melting point of the pitch. In testing the original materials the initial temperature shall be 4° C (40° F).

"**Water-Gas Tar Cement.** The specific gravity at 25° C (77° F) shall be between 1.155 and 1.170.

"On extraction with cold carbon disulphide at room temperature for 20 min, not less than 97.5% shall be soluble.

"When tested in a penetrometer at 25° C (77° F) with a No. 2 needle under 100 g load for 5 sec, it shall have a penetration of not less than 27.5 mm and not more than 32.5 mm.

"When 100 cm are distilled in a 250-cc Engler flask, according to the method proposed by the Am. Soc. Test. Mat., the loss by weight shall be within the following limits:

From start to 170° C	0
170° to 225° C	not over 0.5%
225° to 270° C	from 2 to 6%
270° to 300° C	from 5 to 9%
Residue	not less than 84%."

Modified Topeka Pavement: Wash. State Highway Dept. 1917 Specifications.

"**Materials and Equipment.** The materials and equipment necessary for laying this pavement shall conform in all respects to the material and equipment as specified for Standard Asphalt Pavement except as herein otherwise noted.

"**Crushed Rock or Gravel.** Crushed rock or gravel shall be made from clean gravel or stone, hard, durable and uniform in quality, which shall show a coefficient of wear

in excess of 10, as determined by the Deval abrasion test, and a hardness in excess of 15, as determined by the Dorry hardness test, all tests being under the conditions and methods employed in the U. S. O. P. R. The rock shall be crusher run and shall contain all the fine material, none of which shall be coarser than will pass a ½-in screen. It is further provided that where gravel is crushed for this work, no gravel shall be fed to the crusher smaller than 1 in in diameter.

"Crushed Rock Screenings. Crushed rock screenings shall be of the same quality of stone as above described, and so graded that all shall pass a ¼-in screen and all be retained on an 8-mesh sieve.

"The Mixture shall consist of sand, crushed rock or crushed gravel, ground rock or cement filler and asphaltic cement.

The grading of the finished pavement shall be as follows:

Rock passing ½-in screen, retained on ¼-in screen......	15	to 30%
Rock passing ¼-in screen, retained on ⅛-in screen......	7.5	to 15%
Sand passing 8-mesh sieve and retained on 200-mesh sieve	30	to 60%
Dust filler passing 200-mesh sieve....................	10	to 15%
Asphaltic cement......................................	7	to 11%

"The sand and crushed rock entering into the mixture must be thoroly dry. The sand, rock and asphaltic cement must be maintained at approximately the same degree of temperature at the time of mixing.

"The Sand shall be clean material, hard, durable, and uniform in quality, free from soft materials, mica or other deleterious matter and shall be graded within the following limits:

From 0 to 2% shall be retained on 10-mesh sieve;
From 1 to 5% shall be retained on 20-mesh sieve;
From 3 to 8% shall be retained on 30-mesh sieve;
From 5 to 13% shall be retained on 40-mesh sieve;
From 7 to 17% shall be retained on 50-mesh sieve;
From 20 to 36% shall be retained on 80-mesh sieve;
From 8 to 16% shall be retained on 100-mesh sieve;
From 10 to 15% shall be retained on 200-mesh sieve.

"To insure the maintenance of an even grading in this mixture, three or more divisions must be made of the various sized particles in the aggregate.

"Proportioning. Proper proportions of these materials, together with the asphaltic cement, must be accurately weighed out, and the mixing so handled that each particle of this aggregate shall be thoroly and evenly coated with asphaltic cement, and an even distribution of the various sizes of aggregate in the mixture accomplished.

"This mixture shall be hauled to the street in suitable covered conveyances and shall be spread on the prepared, clean, dry base by shovelling and raking in a manner that will insure an evenly graded mixture that, when thoroly tamped and rolled, shall show an even true surface.

"Flush Coat. Over this shall be spread a thin even flush coat of asphaltic cement made by heating together refined asphalt and flux to a consistency of 140, Dow, at a temperature of about 93° C (200° F), this to be immediately followed by sweeping on an even coating of hot crushed rock screenings or coarse sand, all passing a ¼-in screen and retained on a 10-mesh sieve. The flush coat shall be applied with a suitable machine provided with a flexible band which will insure the quick, even spreading of hot material. Brooming will not be permitted.

"Rolling. The rolling shall be performed with 2½ and 8-ton rollers, continuously until the mixture is cold and in any case to continue for 2 hr after initial rolling. The final thickness of the asphaltic concrete wearing surface shall not be less than 2 in.

"Temperature. The temperature of the mixture at the time of placement in the street shall not be less than 93° C (200° F), and at no time shall it be greater than 149° C (300° F)."

Topeka Pavement, Using Bituminous Sand in the Mineral Aggregate: Cal. State Highway Dept. 1917 Specifications, in abstract.

"Paint Binder. While the concrete foundation is thoroly dry, it shall be cleaned to the engineer's satisfaction and its entire surface area coated with an asphaltic paint binder. The paint binder shall be applied with brooms in sufficient proportion and quantity to give a thin, uniform, black glossy film of asphalt which will harden

within 2 hr after application. The paint binder shall be composed of 1 part by volume of asphaltic cement of 80 to 90 penetration, to from 1 to 2 parts by volume, as directed by the engineer, of engine distillate of the lightest gravity of a quality approved by the engineer. The cost of the paint binder shall be considered as included in the price for asphalt surface.

"Asphalt Surface. Upon the concrete foundation prepared as above described and as soon as the paint binder has hardened shall be laid the asphalt surface, 1½ in in thickness, composed of broken stone or gravel, sand, stone dust and asphaltic cement or bituminous sand, the different ingredients being mixed in such proportion that the percentage composition, by weight, of the asphalt surface shall be within the following limits:

"Bitumen soluble in cold carbon disulphide between 7.5% and 10%.

"Broken stone or gravel, sand, stone dust and other inorganic ingredients, as follows:

Passing 200-mesh sieve, between 8% and 13%
Passing 80-mesh sieve, and rejected by 200-mesh sieve, between 14% and 25%
Passing 40-mesh sieve, and rejected by 80-mesh sieve, between 17% and 29%
Passing 10-mesh sieve, and rejected by 40-mesh sieve, between 5% and 11%
Passing 4-mesh sieve, and rejected by 10-mesh sieve, between 15% and 25%
Passing 2-mesh sieve, and rejected by 4-mesh sieve, between 3% and 10%
All to pass a 2-mesh sieve.

"At least 8% and not more than 17% of the asphalt surface mixture shall be stone dust.

"If the Surface Mixture is Prepared with Bituminous Sand, the following definitions, methods of preparation and tests shall be used.

"DEFINITION. The term bituminous sand shall herein be defined to mean a natural, solid mixture of silicious sand, with a heavy asphaltic petroleum, or heavy hydrocarbons mainly of an asphaltic nature, in which the sand shall predominate in quantity and with which may be naturally combined a small proportion of calcareous matter, infusorial earth, silicate of alumina, or trace only of other impurities not detrimental to the uses of the material as a proper road surfacing.

"PREPARATION. If the bituminous rock in its crude state fails in any particular to satisfy the tests hereinafter provided or the requirements of paragraphs (entitled Asphalt Surface) of this section it shall be crushed or disintegrated by suitable means and its deficiencies shall be corrected by the careful application of heat and by mixing therewith stone dust and sand or asphaltic cement, all of such character and in such proportions and manner as to insure a homogeneous mixture of all ingredients that will fulfil the said requirements and the following tests.

"TESTS. The total bitumen contained in the mixture as determined by solution in carbon disulphide shall be soluble in cold carbon tetrachloride to the extent of at least 97.5%, and in petroleum naphtha of 86° B to the extent of not less than 70% nor more than 90%. When 50 g of the mixture are heated for 5 hr at a uniformly maintained temperature of 163° (325° F) in a tin box 2½ in in diameter, after the manner officially prescribed, it shall not lose over 0.65% in weight."

Bitulithic Pavement: Am. Soc. Mun. Imp. 1917 Specifications. For specifications for subgrades, drainage and foundations, see Art. 4.

"Wearing Surface. On the foundation prepared as herein above specified, shall be laid the Bitulithic Wearing Surface and Seal Coat, described below, so as to have a thickness of 2 in after thoro compression. The wearing surface shall be composed of hard crushed stone, sand, and Bitulithic Cement.

"The Bitulithic Cement herein specified besides being produced under the direction, processes, supervision and laboratory inspection of, and with ingredients approved by Warren Brothers Co., shall in all respects comply with the specifications for Asphalt Cement contained in the Sheet-Asphalt Specifications of the Am. Soc. Mun. Imp. See Sect. 17, Art. 12.

"Preparation of Bituminous Concrete. Either of the two following methods and apparatus shall be used in the preparation of the wearing surface.

1. The stone and sand shall be heated in a rotary drier and, while still hot, separated into the desired number of different sizes by means of a rotary screen having a minimum screen opening of about 1/10 in and a maximum opening of about 1½ in. The openings in the successive screen sections up to ½ in size, shall not vary more than ¼ in and not more than ¾ in for the sizes larger than ½ in. The aggregate thus

separated shall pass into a bin having sections or compartments corresponding to the screen sections. From these compartments the aggregate shall pass into a weigh box, resting on a multi-beam scale. The desired amount of aggregates from each of the above compartments, shall be accurately weighed separately on the scale and the batch dropped into a twin pug mixer, where it shall be intimately associated and thoroly commingled with a predetermined quantity of Bitulithic Cement sufficient to coat all particles of the aggregate and to fill the voids in sand.

2. The stone and sand shall first be carefully measured as to sizes and a definite quantity of each size shall then be fed into an elevator terminating in a hopper or bin which discharges into a rotary drier or heater, both hopper and heater being so designed as to keep each batch by itself until heated. From the rotary heater the batch of mineral aggregate shall pass into a rotary cylindrical mixer containing blades, spirals or other devices for producing a uniform mixture of the mineral aggregate with a predetermined quantity of the Bitulithic Cement sufficient to coat all the particles of the aggregate and to fill the voids in same.

"The different sized particles of stone and sand, ranging in size from impalpable powder to about one-half the thickness of the waering surface, shall be combined in such proportions as to secure in the mineral aggregate density, or low percentage of voids, and inherent stability or resistance to displacement, producing an aggregate which, when combined with the Bitulithic Cement and laid in place and compacted, will form a street paving structure consisting of mineral aggregate of different sizes and the Bitulithic Cement which permeates the entire mass, fills the voids and unites the various articles thereof. If the crushed stone and sand do not contain enough finely divided particles or impalpable powder to produce a low percentage of voids in the aggregate, the deficiency shall be made up by the addition of any other suitable fine mineral matter.

"**Method of Laying.** The mixture and ingredients thereof shall be maintained at a temperature consistent with good workmanship. The mixture when reaching the street shall be hot enough to allow of being easily spread and raked and shall not be so hot as to injure the Bitulithic Cement.

"**Surface Finish or Seal Coat.** There shall be spread over the Bitulithic surface mixture a seal coat, using per square yard of Bitulithic pavement approximately ¼ gal of Bitulithic Cement, into which shall be incorporated approximately 25 lb of mineral aggregate not larger than ¼ in diameter. After spreading the seal coat, it shall be thoroly rolled into the Bitulithic surface mixture. On grades a coarser aggregate may be used.

"**General.** Each layer of the work shall be kept as free as possible from dirt, so that it will unite with the succeeding layer.

"The bituminous composition or cement shall in each case be free from water and shall be especially refined to remove volatile and other matter susceptible to atmospheric influences.

"Warren Brothers Co., owner of the patents used in the construction of the Bitulithic Pavement, shall file with the proper official or board which is about to receive bids for the work, a properly executed binding agreement to furnish any contractor desiring to bid for the work all the necessary Bitulithic surface material, mixed ready for use, and Bitulithic Cement, and the sand, gravel, or stone screenings for the surface finish course, in accordance with Sections Wearing Surface and Surface Finish, at a definite reasonable price per square yard. Said price shall include a license to use all of the patents required in the construction of the Bitulithic Pavement as herein specified.

"The acceptance of bids by ....
and the letting of a contract for the same shall be deemed by Warren Brothers Co. to be an acceptance of its proposal by ....
....and by the Contractor to whom such contract shall be awarded, and are all that shall be necessary to bind Warren Brothers Co. to said agreement. The filing of a bid under these specifications will be construed as an acceptance of the terms of the license agreement filed, by the Warren Brothers Co., at the price fixed in said agreement, which is on file with the proper official or board."

Bitulithic Pavement: Portland, Ore. 1917 Specifications for composition and manufacture of bituminous concrete for the wearing course.

"**Wearing Course.** Upon the rolled foundation a wearing course of the following proportions by weight shall be laid:

Aggregate passing 1½-in screen and retained on ½-in screen.........	36 to 50%
Aggregate passing ½-in screen and retained on ¼-in screen.........	12 to 20%
Aggregate passing ¼-in screen and retained on 10-mesh sieve........	8 to 12%
Aggregate passing 10-mesh sieve and retained on 200-mesh sieve.....	24 to 32%
Aggregate passing 200-mesh sieve..............................	4 to 7%
Bitulithic cement..	7.5 to 9.5%

"From 50 to 70% of the aggregate passing a 10-mesh sieve shall pass a 40-mesh sieve and from 20 to 35% of the sand shall pass an 80-mesh sieve.

"After the broken stone and sand shall have been heated in a mechanical rotary drier to a temperature of between 121 to 148° C (250 to 300° F), the whole mass shall be elevated and passed thru a rotary screen having circular openings of a maximum diameter of 1½ in and a minimum diameter of 1/10 in. The stone and sand thus separated shall pass into separate bins or compartments, from which they shall be drawn separately into a weigh box in the proportions above specified. If the proper proportion of filler be not obtained from the crushed rock, the deficiency shall be supplied by the addition of hydraulic cement or pulverized stone of an approved quality."

Bitoslag Pavement Specifications, as used in 1918, are as follows:

"Bitoslag wearing surface shall consist of a predetermined combination of properly graded crushed slag, Bitoslag Paving Cement and approved mineral dust or filler. A fundamental feature of Bitoslag construction is the scientific predetermination of the grading of the mineral constituents of the wearing surface above referred to so that the voids of said mineral aggregate shall be filled to the limit to safety, thus insuring in advance a pavement of maximum density and one thereby able to withstand the wear of traffic and action of the elements.

"**Materials.** Slag shall be a carefully selected, air-cooled basic, blast furnace product so crushed that all particles will pass a ¼-in screen.

"Mineral Dust or Filler shall be either Portland cement, pulverized limestone, or other approved finely ground absorbent mineral conforming to the following mesh composition: Passing 200-mesh sieve not less than 65%; passing 100-mesh sieve not less than 85%, total.

"**Manufacture.** Determination of Formula. The volume of voids in the mineral aggregate shall be determined and the amount of bituminous cement to be mixed with the pulverized material to form a filler product shall be established. After this, there shall be added to the mineral aggregate a sufficient amount of the filler product to fill the desired percentage of the void volume previously determined. Upon this basis the requisite quantities of the various constituents shall be computed for the batch formula which shall be adhered to by the licensee.

"Mixing. In preparing the Bitoslag paving mixture at the plant, the crushed slag, after being dried and heated to a temperature of 177° to 232° C (350° to 450° F), shall be measured or weighed into the mixer. The necessary amount of mineral dust or filler shall then be added cold and the two materials mixed mechanically until uniform. To the mineral aggregate, mixed as above described, there shall then be added the predetermined weight of melted and impregnated Bitoslag paving cement and the mixing operation further continued until the entire mass is uniform. On account of the variation, no definite percentage of bitumen can be prescribed for Bitoslag paving mixture. The bituminous aggregate when properly graded, however, shall show not less than 9.5% nor more than 11.5% of bitumen soluble in carbon disulphide. The temperature of the mixture shall be so regulated that it reaches the site of the work within the limits of 149° and 177° C (300° and 350° F).

"**Transportation and Laying.** Promptly after mixing, the Bitoslag paving mixture shall be placed in tight vehicles and transported to the location of the work and during transit it shall be covered with heavy tarpaulins for protection against the weather. On arriving at the site, the mixture shall be dumped at a point sufficiently remote from its place of final deposition to insure all portions of the load being turned over by the shovelers before placing. It shall then be promptly spread to such depth that the resulting layer shall, after compression, be not less than... inches in thickness. Compression shall be commenced as soon after spreading as the mixture has reached the proper temperature, best results being obtained when it has been allowed to cool only sufficiently to prevent adhesion to the roller. The roller shall be of the tandem pattern

weighing not less than 7 ton and the use of water for cooling purposes shall not be permitted on Bitoslag constructions. Rolling shall be promptly and continuously executed so that the proper surface and contour shall be obtained before the paving mixture has so cooled as to become set. During or subsequent to the process of rolling there shall be broomed over the surface a coating of mineral dust, and the rolling continued until cool. The finished highway may be opened to traffic as soon as rolling has been completed."

18. Construction of Asphalt Block Pavements

Composition of Blocks. Asphalt blocks usually have been made of trap rock screenings, mineral dust and asphaltic cement. Good blocks also have been made using copper conglomerate, and, for medium traffic, hard limestone has been used as a substitute for trap rock. The most satisfactory mineral dust, used as a filler, is uniformly pulverized limestone. Portland cement has been used, but it is no better than limestone and costs more. The blocks usually contain from 6.5 to 8% of bitumen.

Grading of Mineral Aggregate for Blocks. The following grading was recommended by the Spec. Com. Mat. Road Cons., Am. Soc. C. E. (17e):

" Passing 200-mesh sieve	20 to 35%
Passing 80-mesh and retained on 200-mesh sieve	7 to 15%
Passing 20-mesh and retained on 80-mesh sieve	12 to 30%
Passing ¼-in screen and retained on 20-mesh sieve	30 to 50%
Retained on ¼-in screen	0%."

Washington, D. C., 1914 Grading (23b), used in asphalt blocks having a bitumen content of 7% and a specific gravity of 2.43.

Passing 100-mesh sieve	22.9%
Passing 20-mesh sieve and retained on 100-mesh sieve	16.3%
Passing ¼-in screen and retained on 20-mesh sieve	59.0%
Retained on ¼-in screen	1.8%
	100.0%.

Shape and Size of Blocks. Well-made asphalt blocks are uniform in composition, texture and shape; have parallel faces; straight, unchipped and unrounded edges, and unbroken corners; and are not warped or otherwise deformed. The usual dimensions of the face of the block subjected to traffic are 5 by 12 in. The blocks are generally manufactured in three thicknesses, 2, 2½ and 3 in. Blocks should not vary more than ¼ in in length and ⅛ in in width and depth from the specified dimensions.

Tests of Blocks by Hemstreet (36). " Some of the more important tests applied to the blocks themselves are determining specific gravity, penetration of block, determination of percentage and character of bitumen, grading of mineral aggregate and water absorption. The specific gravity of the blocks for a known body material and grading is an indication of the lack of voids in the block, but the gravity can be increased by the admission of a percentage of larger stone, at the same time producing a poorer block. The punch test described in the New York State specifications is valuable if the average of a large number of penetrations is determined. Because the punch may strike a large piece of stone, thus giving a false reading, but scant reliance can be placed on the result of only a few tests. The absorption test is of but little use. A block that will absorb 1% of water will be so porous that visual inspection should reject it. It is difficult to completely remove the surface water in order to accurately determine absorption of a fraction of a percent.

" Rattler Test. The most useful test is made by a modified form of the Jones-Talbot rattler, usually known as the Hastings rattler.

"About a square yard of pavement is laid as a lining in a cylinder 37 in in diameter. The blocks are laid with tight joints as on the street and are held in place by clamps on the outer end of the cylinder. Fifty pounds of 2½-in cast iron cubes are placed in the cylinder and as the latter revolves at a speed of 37 rev per min, the cubes are carried up on the side of the cylinder and break over like the crest of a wave, thus producing a pounding, grinding action very similar to that produced by actual traffic. New cubes are used each time and the test is run for 10 000 revolutions. To reproduce climatic conditions the rattler is enclosed in an insulated chamber and the temperature reduced to −4° C (25° F) or lower in order to duplicate average winter temperature and raised to 32° C (90° F) or higher to duplicate summer temperature. This range of temperature of the test is of vital importance, for many asphalt pavements which would be suitable at 25° C (77° F) would fail utterly when subjected to extremes of temperature. The blocks are weighed before and after the test and results are calculated in pounds loss per square yard. The appearance of the blocks after the test is of great importance. They should not become rough or chipped during the cold test nor distorted under the hot test."

Manufacture of Blocks by Hemstreet (36). "The body material is usually crushed trap rock or copper conglomerate. Trap rock is hard, tough and gritty, does not polish under traffic and makes an ideal pavement. Trap is in general use in the eastern and southern states while the companies in the middle west and Canada use crushed copper conglomerate from which practically all the copper has been extracted. The latter material is even harder than trap rock, is tough, gritty, and enormous quantities are available in the copper regions. No matter how suitable the stone used, a poor pavement will result unless it is thoroly clean and freshly crushed. A small percentage of clay or soil is sufficient to form a film over the stone during the heating process. The clay bakes fast to the stone and the insulating coat thus formed prevents proper adhesion between the stone and the asphaltic cement.

"TRAP ROCK ranging in size from 2 to 6 in is procured from a clean quarry and, after crushing, is passed thru rolls and screens. By proper regulation of the machinery, it is possible to produce a uniform and desired grading. Generally the grading is so proportioned that, when the filler has been added, the grading of the total mineral aggregate will be such that practically all of it will pass a ¼-in round hole, about ⅓ being retained on 10-mesh, about ⅓ on 100-mesh, and about ⅓ passing 100-mesh. At least 25 to 30% should pass 100-mesh and the amount retained on 10-mesh may be as high as 40%. The properly graded stone is next heated and the best plants use a type of heater superior to and also much more expensive than the ordinary sand drier. It is 6 ft diameter, 13 ft long, is set level and contains a fixed spiral which guides the material thru at a uniform rate. The material to be heated is in a layer about 2 ft deep and the drum thus contains several tons. As a result the mass heats or cools slowly and the temperature can be regulated with great nicety. The product has a uniform temperature.

"VARIOUS KINDS OF FILLER have been tried such as ground limestone, Portland cement, ground shale, clay, silica, marl, coal, brick, etc. The most acceptable and generally used filler is ground limestone. The grinding may be accomplished by a variety of machines but a preferred type is the Hardinge Conical Tube Mill. This simple machine produces a uniform product. The fineness of the ground limestone or other filler is important and it is quite possible to grind limestone to such extreme fineness that it will be almost impossible to handle the block mixture at the press. All the limestone dust should pass 30-mesh sieve, about 75% should pass 100-mesh and 55% to 60% should pass 200-mesh sieve. A certain amount of 30 and 100-mesh limestone mixed with a harder body material makes a more malleable block than if a smaller percentage of finer limestone is used.

"THE ASPHALTIC CEMENT is a mixture of refined asphalt and flux or asphalts and fluxes used to bind the non-bituminous material. The manufacture of monolithic bituminous pavements is distinctly and decidedly different from the manufacture of asphalt block pavements and a knowledge of sheet-asphalt requirements has sometimes been a stumbling block in the attempted manufacture of asphalt blocks. In order to produce good blocks the asphaltic cement must possess the following characteristics: (1) Sufficient cementing power or adhesion and tensile strength; (2) stability, that is, not to harden or soften with age; (3) non-friable at low temperature; (4) minimum softening under the application of heat; (5) absence of mobile liquid

portions at highest street temperature. Ductility, tho of secondary importance, is necessary in monolithic pavements, for this is the property that provides for expansion and contraction due to temperature changes. In a block pavement the small size of the blocks and the frequent joints provide for this movement. With few exceptions, those cements which are high in ductility are brittle and friable at low temperature while the so-called short cements are tough and malleable when cold. The asphaltic cement must be suitable for the particular climate and kind of traffic under which it is to be used. This is accomplished by varying the kind and amount of flux used with the asphalt. A harder cement is required for use in the tropics than would be used in the climate of New York and a still softer cement is used to advantage in Canada. In order to have joints in the finished pavement iron out under light traffic, a softer cement is used than would be allowable under heavy traffic.

"On the Mixing Platform, the materials are weighed out for each batch according to the formula given to the mixer foreman. The time of mixing each batch is measured by a sand glass so that each batch is mixed for the same length of time. The various receptacles and the mixer itself are carefully and completely covered so that a minimum of dust escapes. The mixer used is a specially designed and very powerful machine consisting of two parallel shafts geared together, carrying heavy, chilled iron teeth which revolve within a chilled iron body. The mixer charge is somewhat as follows: Trap rock, 2500 lb; limestone dust, 750 to 850 lb; asphaltic cement, 820 to 360 lb; total, 3710 lb. The carefully proportioned and properly mixed material is next fed to a huge hydraulic press. The mold is opened, filled, closed, and the enormous pressure of 240 tons is applied to each block. The pressure is then removed, the mold uncovered and the block ejected and measured. Any variation is multiplied by 10 and shown on a dial. After measurement the block moves forward onto a conveyor belt and is carried under water for 150 ft and is then cooled and ready for use. Each press will produce 36 000 blocks per day."

Method of Laying. Asphalt block pavements should be laid on a strong foundation, usually of cement-concrete at least 5 or 6 in in thickness and, in cases of the heaviest traffic which this type of pavement can carry, 8 or 10 in in thickness. On cement-concrete foundations, the blocks are laid on a ½-in fresh 1 : 4 cement mortar bed. The blocks should be laid with close joints on grades as high as 6%. After being laid, the blocks should be covered with a thin layer of dry, clean, fine, sharp sand, which should be thoroly swept into the joints, and the surplus left upon the surface for at least 30 days. On grades above 6%, ⅜ or ½-in joints filled with Portland cement grout have been used. After the grout has partially set, the joints are raked out to a depth of about ½ in. On roadways subjected to heavy motor traffic, anchor blocks should be used. For description of anchor blocks, see Art. 19.

19. Specifications for Asphalt Block Pavements

N. Y. State Highway Comm. 1917 Specifications are as follows:

"**Size and Composition.** The blocks shall be 5 in in width, by 12 in in length, by 2 in in depth, and a variation of more than ¼ in in length or ⅛ in in width or depth from these dimensions will be sufficient ground for rejecting any block. The blocks shall consist of the following materials: Asphaltic cement; approved crushed trap rock or approved crushed limestone; inorganic dust.

"**The Asphaltic Cement** shall have the following characteristics:

1. It shall be free from water.
2. The various hydrocarbons composing it shall be present in a homogeneous solution.
3. It shall have a specific gravity at 25° C (77° F) of not less than 0.97.
4. The penetration shall be between 1.5 and 2.5 mm when tested for 5 sec at 25° C (77° F) with a No. 2 needle, weighted with 100 g.
5. Fifty grams of it upon being maintained at a uniform temperature of 163° C (325° F) for 5 hr in a cylindrical vessel, 5½ cm in diameter by 3½ cm high, shall not lose more than 2% in weight. The penetration at 5 sec, 25° C (77° F), No. 2 needle, 100 g weight, of this residue shall be at least 60% of the original penetration.

6. Its solubility at air temperature in chemically pure carbon disulphide for the following named materials, or materials similar thereto, shall be at least 99.5% for pure bitumen products, 96% for Bermudez products, 81% for Cuban products and 66% for Trinidad products.

7. The solubility of the bitumen at air temperature, in 76° B paraffin petroleum naphtha, distilling between 60° and 88° C (140° and 190° F), shall be between 65 and 80%.

8. The bitumen shall show between 8 and 18% fixed carbon.

9. It shall show an open flash point not less than 190° C (375° F).

10. It shall not contain more than 2% paraffin scale.

11. It shall show a toughness at 0° C (32° F) of not less than 10 cm. Toughness is determined by breaking a cylinder of the material 1¼ in in diameter by 1¼ in in height in a Page impact machine. (Am. Soc. Test. Mat., Aug. 15, 1908.) The first drop of the hammer is from a height of 5 cm and each succeeding blow is increased by 5 cm.

12. It shall have a ductility at 25° C (77° F) of not less than 8 cm, Dow mold.

"**Mineral Aggregate.** The crushed rock for coarse aggregate used in the blocks shall be crushed from clean hard rock and shall not contain any soft ingredients. It must be crushed so that every particle will pass a ¼-in screen.

"The inorganic dust, or filler, shall be produced from sound limestone, and shall be powdered to such a fineness that all of it shall pass a 30-mesh sieve and not less than 50% of it shall pass a 200-mesh sieve. Sufficient inorganic dust shall be used to give a minimum percentage of voids in the block, and provide a sufficient medium for absorbing the asphaltic cement.

"The block composition shall yield not less than 6.5 nor more than 8.5% of bitumen, when extracted with carbon disulphide.

"GRADING. The mineral aggregate of the blocks shall meet the following mesh analyses:

Passing 200-mesh sieve, at least	18%
Passing 80-mesh sieve, retained on 200-mesh sieve	12 to 18%
Passing 40-mesh sieve, retained on 80-mesh sieve	8 to 14%
Passing 20-mesh sieve, retained on 40-mesh sieve	8 to 16%
Passing 10-mesh sieve, retained on 20-mesh sieve	15 to 20%
Passing ¼-in screen	100%

"**Manufacture.** The use of dust coated screenings will be cause for rejection. The blocks shall receive a compression in the molds of not less than 200 tons.

"**Tests of Blocks.** The blocks shall have a specific gravity of not less than 2.45 for trap blocks, or not less than 2.30 for approved limestone blocks.

"After having been dried for 24 hr, at a temperature of 66° C (150° F), the blocks shall not absorb more than 0.75% of moisture when immersed in water for 7 days.

"The average penetration of a block shall not exceed ¼ in when tested for 1 min at a temperature of 38° C (100° F) with a cylinder ¼ in in diameter loaded with 147 lb.

"**Laying.** Upon the foundation shall be spread a bed of the thickness shown upon the plans, composed of 1 part Portland cement and 4 parts sand, thoroly mixed with sufficient water to make a stiff paste. This mortar bed shall be struck with a template to a true surface exactly parallel to the top of the proposed pavement surface and 2 in below it.

"The blocks shall be laid while the mortar is fresh and before it has begun to harden. All depressions and other irregularities in the surface shall be corrected by the contractor immediately. The blocks shall be laid by the pavers standing upon the blocks already laid and not upon the bed of mortar. The blocks shall be laid at right angles with the line of the street, and in such a manner that all longitudinal joints shall be broken by a lap of approximately 4 in. The blocks shall be so laid as to make the lateral joints as tight as possible, consistent with keeping a good alignment of the courses across the street. When thus laid the blocks shall be immediately covered with clean, fine sand, perfectly dry, screened thru a ⅛-in screen. This sand shall be spread over the surface and swept into the joints and be allowed to remain on the pavement not less than 30 days or until the action of the traffic on the street shall have thoroly ground the sand into all the joints.

"**Anchor Blocks and Strips.** On grades, curves or elsewhere as shown on the plans or as ordered by the engineer, blocks containing an imbedded anchor of iron or steel of an approved shape shall be furnished. Steel strips, 1½ in wide, ⅛ in thick and

from 2 to 4 ft long may be set on edge between courses as a substitute for anchor blocks. These anchor blocks or steel strips are to be laid in such courses and at such intervals as shown on plans or as directed by the engineer."

N. J. State Highway Dept. 1917 Specifications covering manufacture of blocks and anchor blocks are as follows:

"**Manufacture.** When compounding the above ingredients the trap rock and asphalt cement shall each have a temperature of not less than 121° C (250° F) nor more than 177° C (350° F). They shall be blended in an asphalt mixer of the pug mill type. The trap rock and filler shall be thoroly and uniformly mixed together before the hot asphaltic cement is added. After the asphaltic cement has been added, the mixing shall continue for at least 3 min and as much longer as is necessary to secure a homogeneous mixture in which all the particles are thoroly coated with the asphaltic cement. The above mixture must have a temperature of not less than 121° or over 163° C (250° or over 325° F) and while at this temperature shall be formed into blocks of the specified size under a pressure of not less than 6000 lb per sq in applied on the major face. After compressing they shall be cooled immediately in the manner required.

"**Anchor Blocks** shall, in addition to meeting the requirements specified hereinabove, have a strip of sheet iron 0.083 in in thickness and 1 in wide so imbedded in the block that it is firmly held in place, does not project less than 3/8 in or over 1/2 in below the surface of the face of the block, is elliptical in shape, the major axis of which is not less than 9 in or over 10 in and the minor axis, not less than 2 1/2 in or over 3 in."

20. Miscellaneous Bituminous Pavements Constructed by Mixing Methods

Sand Mixed with Asphaltic Oil or Asphalt Cement. The Mass. Highway Comm. has endeavored since 1908 to develop an efficient method of utilizing the local sand on Cape Cod in the construction of a type of bituminous pavement suitable for the traffic to which many of the highways in the southeastern section of Massachusetts are subjected. The conclusions and specifications of the Commission cover the fundamentals of this type of construction.

Mass. High. Comm. Report, 1915. "In the fall of 1908, the Commission decided to try some experiments with various bituminous materials mixed with hot sand. Eleven sections of road were constructed and a different bitumen was used on each. Two qualities of tar were used and nine different oils or asphalt products. In each case the subgrade was carefully prepared of the required width, and the mixture was spread as evenly as possible thereon and rolled with a light roller. The mixture was 4 in thick in the middle and 3 in thick on the sides. The sand and the bituminous materials were first heated, and then mixed by hand as thoroly as possible, before being spread on the road. Eight of these experimental sections practically failed within the year. Another section was never very satisfactory, and only two remained in good condition and are still in use, having been patched from time to time. The only sections that succeeded were the ones where a heavy oil with an asphalt base was used, or where this oil was used mixed with an equal quantity of asphalt. This latter section was much better than the other two. The daily traffic that has been carried successfully as shown by the traffic census taken in 1910, 1912 and 1915 is about as follows: Sandwich Road: 8 heavy teams, 23 light teams and 502 automobiles; Plymouth Road: 3 heavy teams, 8 light teams, 257 automobiles.

"The Commission has constructed over 23 miles of mixed sand and oil asphalt roads since the experiments made seven years ago in 1908. It has also built over 1 1/2 miles of sand mixed with tar. The roads are built over a carefully prepared and hardened base, about 4 in thick in the middle and 3 in on the sides, 18 ft in width, with 21 ft on the curves.

"Various asphalts have been used, both residuum and natural, and on this mixed work an oil asphalt is now used that tests 80 penetration on a Dow penetrometer. The quantity of oil asphalt that is used has to be varied a little according to the variations in the quantity of voids in the sand, 18 to 21 gal being used to 1 cu yd of sand.

"New mixing machines have been made, and their use insures a much more even mixture of the sand and oil. Several sand heaters have been designed and have been used with good results. In these the sand is kept in motion all the time it is being heated, insuring a uniform heating of the sand. Better results have been secured by using a road scraper and keeping the mixture constantly shaped while it is being rolled. As stated above a seal coat of a lighter oil improves the road surface and prevents it from having occasional pot-holes, and decreases the cost of future maintenance.

"The cost of these sand and oil asphalt roads has varied from 40 to 61 cents per sq yd, the average cost being 52 cents.

"There is no class of road built that will go to pieces any quicker than roads of the above character, if they are not constantly maintained. A pot-hole in wet weather will soon become as big as a bushel basket, and with many holes of this kind the road is not only very quickly destroyed by the traffic but it becomes impassable. Thousands of dollars are lost every year because this maintenance is neglected, the holes not being filled.

"The average cost of maintenance per year on these mixed roads that have been in use 5 years has been 1.6 cents per sq yd per year; on roads that have been in use 3 years the yearly cost of maintenance has been 0.75 cents per sq yd. If these roads require a seal coat every 4 or 5 years, as seems probably, the average yearly cost of maintenance will be about 2½ cents per sq yd per year."

The Mass. Highway Comm. Specifications (30b), in part, are as follows:

"METHOD OF MIXING. The sand and oil shall be mixed by hand or in a mechanical mixer. If by hand, the mixing shall be done on platforms with rakes and hoes, or by turning with shovels. The platforms shall be made of 2-in planks, and shall be about 8 ft wide by 16 ft long, but for convenience in handling may be made in 2 sections. If a mechanical mixer is used, it shall have a suitable hot attachment, so arranged that the materials will not be burned during the mixing.

"The oil or oil asphalt used for mixing shall be as ordered, but in no case shall oil having a viscosity of less than 500 sec, Lawrence Viscosimeter at 100° C (212° F) or oil asphalt having a penetration of less than 60, Dow penetrometer at 25° C (77° F) be used. The amount of oil used shall be as ordered, but in no case shall less than 15 gal or more than 20 gal be used per cu yd of loose sand. The oil shall be heated to a temperature of from 121° to 191° C (250° to 375° F), depending on the nature of the oil or oil asphalt used.

"The sand shall be clean, sharp, fairly coarse and well graded, and shall contain no adventitious material of any kind. It shall contain no stones more than ½ in in their longest dimensions, or over 52% passing a 50-mesh sieve. The sand when mixed with the oil shall be dry and so heated, that a uniform mixture will be secured. Care must be exercised not to overheat the sand so as to burn the oil.

"METHOD OF LAYING. When the mixing is completed to the satisfaction of the engineer, it shall be transported immediately to and spread on the road. It shall not be dumped directly on the subgrade, but upon dumping boards or iron plates; the dumping boards or plates to be of sufficient size to retain all of the mixture when dumped. The mixed material after it is deposited in place shall be shaped with rakes and immediately rolled with a horse roller weighing about 1 ton. The surface shall be shaped with a road machine or suitable scraper and afterwards rolled with a tandem steam roller. The length of time elapsing before rolling with the steam roller shall be as ordered by the engineer. Any depressions appearing in the surfacing shall be filled with mixed material satisfactory to the engineer. If such depressions are found after the sand and oil have hardened so the new material will not bond readily with the old, a sufficient amount of the old material shall be dug out to allow the placing of not less than 2 in of the new mixture, which shall be thoroly rolled. Any slight unevenness of the surface shall be remedied by scraping with a road machine or suitable scraper and the surface again rolled.

"SEAL COAT. After the sand and oil mixture has been shaped and rolled to the satisfaction of the engineer, a seal coat of asphaltic oil shall be distributed on the surface in 2 applications of ¼ of a gal per sq yd. Each application of oil shall be covered with a thin layer of sand spread evenly over the surface and rolled with a steam roller, additional sand being added as needed to absorb any flushing to the surface. The asphaltic oil used for the seal coat shall be of a grade satisfactory to

the engineer, but in no case shall oil having a viscosity of less than 250 sec, or more than 600 sec, Lawrence viscosimeter at 100° C (213° F) be used. The oil shall be heated in tank cars or otherwise and shall be transported to the work in suitable distributor carts or trucks. It shall have a temperature of approximately 121° C (250° F) when applied. The oil shall be applied by a pressure distributor which will spread it evenly over the surface, leaving no spots or streaks uncovered, and no overlapping will be allowed.

Clay or Loam Mixed with Asphalt Cement. In 1912 a mixture of pulverized clay and asphalt cement was laid in Iola, Kan. Since 1912 several sections of this type of bituminous pavement have been laid thruout the United States.

Method of Construction (51b). "In constructing this pavement, a specially designed machine thoroly pulverizes the soil which is fed into it, which may be that excavated from the road in grading, at the same time evaporating the moisture contained therein and heating all material to the degree necessary for uniform and easy mixing. There are two drums, the inner of which has blades on the outer circumference. The outer drum acts as a heater. The inner revolves at a rate of about 600 rev per min, and the blades, which are arranged normal to a helix so that the material is worked toward one end, throws the material against the outer drum. It is raised by flights on the inner surface of the outer drum, which revolves slowly, and as it falls back it is again caught by the blades, this process being repeated until all the earth is pulverized completely and comes out as flour. A screen prevents unpulverized particles from coming out. Any sand particles come out clean and bright. The bituminous binder is then mixed with the pulverized, dried and heated material in a regular asphalt mixer. The product as it comes out resembles pulverized rock asphalt more than it does sheet-asphalt, tho it can be handled in the same way as the latter. It is hauled to the road, spread, and rolled when sufficiently cool. The material which has been used as mineral aggregate in Iola is a clayey sub-soil excavated from the street to be paved. This material, which is commonly known as gumbe soil in the middle west, is considered the most refractory soil or clay to work up into paving, yet it was readily pulverized and mixed with the asphaltic cement."

Report by Dow (51b). "The National pavement is composed of asphalt cement mixed with pulverized clay or loam which may contain more or less sand or fine stone. Owing to the strong affinity for bituminous materials like asphalt cement possessed by the colloidal silica and silicates contained in clay and clayey soils, and also to the fine state of division of the pulverized clay, a very soft asphalt cement may be used in the mixture without danger of producing a pavement too soft for traffic. In this respect it has a distinct advantage over other types of bituminous pavements, for it is a well known fact that the softer the asphalt cement used the longer the life of the pavement, provided it is not so soft as to roll under the traffic. As to the wearing qualities of this paving material no one can say from a practical experience, but, judging from its characteristics, it is hard to appreciate how it can be worn away. The wearing can not take place in a manner similar to the other types of bituminous pavements constructed with sand and coarse mineral aggregate. In these materials, the coarse mineral matter slowly pulverizes under traffic and grinds away, but in the case of the National pavement the clay is already pulverized to as fine a condition as possible and there can not be any further grinding of the particles. One great advantage which this paving material possesses over that of other bituminous pavements is that it is made of finely pulverized clay with little or no gritty particles contained in it. It will not have the same wearing effect on rubber-tired vehicles which are now so much in use on our public highways."

In a later report (1917) Dow states that, "as the National pavement is composed of the finest divided mineral particles which present a large surface area to be covered with bitumen, its asphalt contents is much greater than that of any other type of bituminous pavement, thus making it a more malleable material. This great malleability will prevent the formation of cracks and depressions in the pavement when it is subjected to traffic, and will tend to keep the surface smooth and uniform and free from ruts."

Specifications for National Pavement are, in part, as follows: "Upon the foundation prepared and laid as elsewhere herein specified shall be laid the pavement proper.

This shall consist of a bituminized earth wearing surface ... inches in thickness composed of: Pulverized clay, loam or earth, 80 to 85%; asphalt cement, 15 to 20%.

"ASPHALT CEMENT. It shall have a penetration at 25° C (77° F) of from 80 to 150 depending on the fineness of the pulverized earth, the traffic, and the local climatic conditions.

"PULVERIZED EARTH, CLAY OR LOAM. This shall be an earthy material complying with the following requirements, the tests being made on the dried material.

1. Upon sifting it shall have the following mesh composition:

Passing 200-mesh sieve	50 to 100%
Passing 50-mesh sieve, and retained on 200-mesh sieve	0 to 30%
Passing 20-mesh sieve, and retained on 50-mesh sieve	0 to 20%

2. When the earth, clay or loam is worked into a stiff paste and molded into a standard cement briquette it shall, after drying, show a tensile strength of not less than 50 lb per sq in.

3. It must be soluble in dilute hydrochloride acid (1.2) to the extent of not less than 5 nor over 15%.

4. The pulverized earth must not contain more than 5% of carbonates.

5. On igniting at a red heat, it shall lose between 3 and 12%.

"WEARING SURFACE. The earth must be heated and pulverized by passing thru a revolving drum containing a disintegrator of approved type. The pulverized earth when used must be at a temperature between 93° and 149° C (200° and 300° F). The asphalt cement when used must be at a temperature between 121° and 149° C (250° and 300° F). The pulverized earth and asphalt cement shall be brought together and mixed for at least 1 min in a suitable appliance until a homogeneous mixture is produced in which all the particles are thoroly coated with asphalt cement.

"LAYING. The surface mixture prepared in the manner above described shall be brought to the work in wagons and upon reaching the street, shall have a temperature between 93° and 135° C (200° and 275° F). The temperature of the surface mixture within these limits shall be regulated according to the temperature of the atmosphere and the working of the mixture and the character of the materials employed. On reaching the street it shall at once be dumped on a spot outside of the space on which it is to be spread. It shall then be deposited roughly in place by means of shovels, after which it shall be uniformly spread in place by means of hot iron rakes in such a manner that after having received its final compression by rolling the finished pavement shall conform to the established grade. The thickness of the finished surface mixture shall average 2 in. Not more than 10% variation from the average thickness specified will be permitted in any one spot. After raking, the surface mixture shall be compressed by rolling or tamping. After it has received its first compression and has cooled sufficiently, the surface shall then be thoroly compressed by a steam roller weighing not less than 200 lb per in width of tread, the rolling being carried on continuously at the rate of not more than 200 sq yd per hr per roller until a compression is obtained which is satisfactory to the engineer."

Wood Fibers Mixed with Bituminous Cement. In 1911 an experimental section of bituminous pavement of this type, known as Fibred-Asphalt, was constructed in St. Albans, W. Va. under the direction of the patentee, Geo. H. Henderson. Since 1911, sections have been constructed in several states, including Delaware, New York, and Tennessee.

Method of Manufacture and Construction (27a). "This pavement consists of the fibers of hard wood, impregnated with a preservative compound and bound with a bituminous material. The fiber used is the toughest sinew of hard wood remaining after the deteriorable, evaporable sap, essences and softer portions of the wood have been extracted and removed. It is obtained as a by-product of the manufacture of tannin and other essences. In preparing the material for pavement purposes, the fibers are removed from the extract vats by endless belts and conveyed to vacuum driers. After being dried they are screened, the largest chip used being that passing a 3-mesh sieve. Four different sized sieves are used, the various sizes of chips being afterwards mechanically mixed in the predetermined proportions, from the larger sizes down to wood flour. The dry graded chips are next conveyed to a mixer, where the impregnating preservative is added, and are then coated with molten asphalt.

The mixture is next discharged into molds 4½ ft by 6½ ft and compressed into 4 ft by 6 ft blocks ready for shipment.

"In laying the pavement the prepared material is shipped in blocks to the site of the work. The blocks are then chopped up into 3 or 4 pieces and placed in a special portable reheating machine, from which the material is discharged hot onto the prepared road-bed, and mechanically spread by an attachment to the machine to a uniform depth of 4 in uncompressed. The hot material is then tamped by hand by large wooden tamps, first dipped in water to avoid picking up the sticky material. The tamping operation is followed by a series of steam rollings until the material is compressed to a compact, homogeneous mass 2 in thick, this constituting the wearing surface of the road. The cost of the reheating machine complete is $2500, and it is stated that the entire force required for its operation, including shaping and tamping of the mechanically spread material, consists of 1 expert, 1 foreman, 1 engineer and 12 laborers. In addition there will be the steam roller operators. The cost of the prepared material f.o.b. cars is stated to be about 42 cents per sq yd of finished road, and it is further stated that 2-in pavement can be constructed at a cost of about 60 cents per sq yd, this including royalties, labor and all charges."

21. Construction Cost Data

The cost of bituminous concrete pavements varies with the kind and quantity of bituminous material used, the character of the aggregate and the method of construction employed. Using an aggregate of stone varying from ⅛ to 1¼ in in longest dimensions, mixed with 5 to 8% of bitumen, and a seal coat of ¾ gal per sq yd, the cost of a 2-in wearing course should be 30 to 50 cents per sq yd in excess of water-bound broken stone roads. The cost of pavements of Classes B and C usually varies from $1 to $2.50 per sq yd, including foundations and light grading. Asphalt block pavements on 5 or 6-in cement-concrete foundation vary in cost from $2 to $3 per sq yd.

Records of Cost Data for Class B Pavements by White (73a). In describing the construction of bituminous concrete pavements, South Park, Chicago, the following details of recording costs of operation of a Link-Belt Portable Asphalt Plant and the laying of the daily output, which frequently amounted to 1250 sq yd of 2-in surface, are cited.

"The surface foreman's report on work order No. 2201 of the same date records: Date; work number; location of work; thickness of asphaltic concrete laid; square yards of each thickness; number and duties of each man employed; number of hours and rate per hour of each man; total batches received from each asphalt plant; number gallons for squeegee; number cubic yards and kind of sand; number of pounds of coal.

"The surface foreman's labor report on work order No. 2201 of the same date also records:

Number of men	How Occupied	Rate per Hour in Cents	Hours Worked
1	Top foreman	40.0	9.0
4	Laborers raking	38.0	42.0
1	Laborer tamping back	38.0	10.5
2	Laborers tamping	32.0	21.0
4	Laborers spreading	27.0	42.0
1	Laborer dumping carts	27.0	11.5
1	Laborer painting joints	27.0	11.5
1	Laborer spreading sand	25.0	10.0
1	Timekeeper	27.5	2.0
2	Ten-ton rollers	55.5	21.5
1	General foreman	55.6	1.0

"The daily report of the asphalt plant foreman records: Date; work number; location of work; total batches delivered by each asphalt plant; hours delay and cause; number and duties of each man employed; number of hours and rate per hour of each man; amount of asphalt used; amount and kinds of stone used; amount and kinds of sand used; amount of coal used; amount of gasoline used.

"In order to illustrate the data as to number, rate, and hours of men employed in the asphalt plant crews, the asphalt plant foreman's report on work order No. 2201 of July 1, 1912, is quoted as follows:

Number of Men	How Occupied	Rate per Hour in Cents	Hours Worked
1	General construction foreman	55.6	1
1	Asphalt plant foreman	33.8	9
1	Traction engineer	55.5	12
2	Firemen	29.7	18
4	Asphalt cutters	25.0	36
4	Tankmen	25.0	36
6	Feeders	25.0	54
4	Mixers	25.0	36
2	Coal men	25.0	18
6	Men cleaning up	21.8	54
4	Linemen	25.0	36
1	Oiler, machine tender	30.0	12
4	Carts hauling hot ashpalt	50.0	24
4	Carts moving material	50.0	12
1	Team cleaning up	68.7	9
1	Timekeeper	33.8	2
2	Timekeepers	27.1	4
2	Watchmen	25.0	18
1	Water boy	12.5	8

Cost Data Relative to Class B Bituminous Gravel Concrete Pavement built in 1916 on the Alexandria-Accotink Road, Fairfax County, Va., under the direction of the U. S. O. P. R. (67d). For details of construction, see Art. 14.

Unit Prices of Labor, Teams and Trucks: Foremen, rollermen and skilled laborers, $4 per 8-hr day; common laborers, $1.60 to $2.00 per day; teams, $4.50 per day; trucks, $1 per hr.

Labor Costs in cents per sq yd: Hauling asphalt, 1.424; mixing, 15.156; hauling mix, 6.64; setting headers, 1.421; spreading mix, 3.627; rolling, 0.765; sealing, 1.315; hauling pea gravel, 0.777.

Costs of Materials: Gravel, 10 cents per cu yd and 0.91 cents per sq yd of 2 in wearing course; asphalt, $15 per ton and 14.59 cents per sq yd; limestone dust, $6 per ton and 1.53 cents per sq yd; pea gravel for seal coat, $1.50 per ton and 1.42 cents per sq yd.

Total Cost: Labor per sq yd, 31.13 cents; material for bituminous concrete per sq yd, 18.45 cents; total cost of 2-in bituminous gravel concrete wearing course, 49.58 cents per sq yd.

Cost Data Relative to Topeka and Bitulithic Pavements. In Tables IV and V are given, for several localities in the United States, 1916 prices of Topeka and Bitulithic pavements on cement-concrete foundations.

Cost Data Details of Topeka Pavement in Holland, Mich. (51a). "The paving proper consisted of 6 in of Portland cement-concrete and 2 in of asphaltic concrete; the latter being the combination known as Topeka specification. The material for the bituminous wearing surface cost as follows: Pioneer asphalt, 10.1 cents per gal; stone, ½ in, $1.20 f.o.b. on the dock, average haul, 1 mile; sand, 90 cents per yd. Teams cost $4 per day; labor, $2 per day on a 9-hr basis; and an inspector and foreman combined, $5 per day.

Table IV.—Cost of Topeka Pavements in 1916 in Several Cities
From *Engineering and Contracting*, April 4, 1917

City	Square Yards	Price* per Sq Yd	Guarantee Years	Wearing Course Thickness Inches	Concrete Foundation	
					Thickness Inches	Proportions
Albany, N. Y.	13 393	$1.71†	5	2½	6	1:3 :6
Harrisburg, Pa.	10 361	1.33†	5	2	4	1:3 :5

*Price covers pavement, foundation, and shaping subgrade.
†Does not include shaping subgrade.

"Sixteen men were used in the concrete gang and 13 men in the asphalt gang, the latter including the roller man and engine tender. Two Rapid mixers were used, the same machines being used for both Portland cement-concrete and bituminous concrete. The paving machinery having been purchased by the street fund, 6 cents per sq yd was paid into this fund for the use of the machinery, or a total of $967.26. One hundred dollars was also paid into the same fund for the use of the city roller.

"The 6-in concrete base was put down for 41.2 cents per sq yd and the 2-in asphaltic concrete top for 54.2 cents per sq yd, making a total cost of pavement of 95.4 cents per yd."

Cost Data Details of Bitulithic Pavement in Portland, Ore. (52). "The costs of materials and labor, both at the paving plant and on the street, are based upon daily cost records kept by the Bureau of Standards of the City of Portland in 1915 and 1916 involving the laying of 24 843 sq yd of 2-in Bitulithic wearing surface.

	Per Sq Yd
MATERIALS	
Asphalt cement at $10.50 per ton	$0.128
Sand at $0.45 per cu yd	0.018
Rock screenings at $0.93 per cu yd	0.032
Portland cement	0.000
Crushed rock at $0.93 per cu yd	0.038
	$0.216
MIXING PLANT COSTS.	
Labor	$0.0340
Fuel oil, $1.10 per bbl	0.0190
Lubricating oil	0.0007
Power	0.0030
	$0.0567
HAUL, average of 3 miles	$0.0610
STREET COSTS	
Labor	$0.0430
Coal for roller, $6 per ton	0.0005
Coal oil at $0.10 per gal	0.0004
	$0.0439
TOTAL FOR MATERIAL AND LABOR	$0.3800
OVERHEAD	
Maintenance and repairs to plant and equipment	$0.020
Depreciation and obsolescence of plant and equipment, 20%	0.046
Interest on plant and equipment at 6%	0.014
Supervision and office expense	0.065
Taxes and use of plant site	0.037
Insurance	0.003
Total superintendence and overhead	$0.185
TOTAL FOR PAVEMENT	$0.565

NOTES: The cost allowance of $0.02 per sq yd for maintenance and repairs to plant is based upon the actual guarantee that manufacturers of certain paving plants are willing to make on their plants for a moderate amount of paving.

"The cost factor for depreciation and obsolescence is based upon plant and equipment valued at $15 000 and upon a yearly output of 65 000 sq yd, which was the output of the contractors' plants in 1915. The factor of 20% for depreciation, which is based on the allowance made for depreciation on the District of Columbia paving plant, is liberal, for the Warren Brothers Co. use a factor of 10% depreciation on their plants.

"The cost of supervision and office expense is based upon the following force: A superintendent at $2400 per year, one bookkeeper at $1200 per year, and a stenographer at $600. This force is considered as working thruout the entire year and devoting all its attention to paving, tho in actual practice a force of this kind handles many other contract items than paving in a year's work.

"The cost item of taxes and use of plant site is based upon the payment of a rental of $200 per month for a plant site. This is a far higher rate than probably any of the plants in Portland pay."

MAINTENANCE

22. Causes of Failure

The percentage of failures of bituminous concrete pavements is much smaller than in the case of bituminous macadam pavements. Failures may be considered from the standpoint of inadequate drainage and foundations, the materials employed, and methods of construction adopted. Many failures have occurred because the type of pavement used was not suitable for the traffic or other local conditions. From an economic standpoint, numerous failures are due to inefficient maintenance.

Failures Due to Frost Action on Ashokan, N. Y., Highways (20). "At a number of culverts which had heaved with the frost, a greater thickness than the theoretical 2-in wearing course was necessary as it was considered advisable not to decrease the thickness of the bottom course of crushed stone over the culvert, but to give the road a gentle slope each side of the culvert. Numerous bumps or warts on the road which were removed proved to be caused by the working up of boulders by the frost. The boulders varied in size from 2 to 200 cu ft. These at the time of construction had either been below the sub-grade or had been leveled off to that grade, it being thought better to keep them in place rather than remove them with consequent soft places in the foundation. This work was accomplished with the City's forces by barring and wedging or by light charges of powder."

Materials. Poor and unsuitable materials have been accountable for certain failures. In some cases an apparent cause of failure has been an excess of flux or of the volatile constituents in asphalt cements. Pavements constructed with such materials are frequently wavy, due to the movement of the surface under heavy traffic. The use of bituminous cements having too low penetration has resulted in the cracking or general disintegration of the pavement. Many causes of failure would be eliminated if engineers would devote more time to a consideration of the physical and chemical properties of the materials which they employ. If a bituminous material laboratory is not connected with the department, it should be neither expensive nor difficult to secure certified analyses made by reputable chemical engineers.

Either too large broken stone or stone of too uniform size may cause a failure. Especially is this the case with very hard and tough broken stone. The rocking of the stone causes the formation of fine cracks which eventually lead to disintegration. Poor combinations of sizes of broken stone and sand have resulted in segregation during mixing, transportation or spreading, resulting in a pavement of varying density and stability.

Construction. Many cases are reported where materials have been overheated due to the belief that all materials may be and even should be heated to the same temperature before using and that it is impossible to

injure bituminous materials by heating to high temperatures. Overheating of the mineral aggregate has caused burning of the bituminous material in some instances or the formation of a thin film of bituminous material over the broken stone which is not of sufficient amount to bind the adjacent particles together. The use of a wet aggregate will result in a poor mix with consequent unsatisfactory results. In many instances the seal coat has not been applied uniformly. The result is either uneconomical, due to the necessity of a second application before 75% of the surface requires retreatment, or the disintegration of the pavement whenever bare spots occur in pavements where a coarse aggregate was used and where there is considerable horse-drawn vehicle traffic. Some failures have been caused by using unheated stone with bituminous cements which will not adhere satisfactorily or which mix only with great difficulty under such conditions.

Causes of Waviness by Smith (60a). "Whatever type of construction is decided upon, it must always be borne in mind that a bituminous wearing surface is flexible and will only give good service when it is properly supported by an adequate foundation. Soft spots or weak places in the foundation will cause a settlement of the overlying wearing surface which will result in rapid deterioration. Water will collect in such low spots and rapidly destroy the bond between the bituminous binder and the mineral aggregate. The wheels of each vehicle passing over such depressions will strike a heavy blow as they drop into them and cause displacement of the wearing surface, resulting in the formation of a ridge which still further adds to the vibration of the springs and causes successive blows to be dealt to the pavement until the spring vibration becomes normal again. This, of course, results in the formation of waves. In most heavy commercial vehicles the springs are comparatively short and stiff. The vibrations are, therefore, quick and tend to strike very heavy blows, resulting in wave formation at right angles to the line of traffic having their crests from 3 to 4 ft apart. This is plainly noticeable on roads having a bituminous wearing surface and it is still more evident on water-bound macadam roads. The poorer and less rigid the foundation the more pronounced the waves. This is quite distinct from the shearing or shoving action exerted by vehicles rounding curves at a moderately high rate of speed. The motor-bus is perhaps more directly responsible for this type of wave formation than any other modern type of vehicle. In England, more especially in the neighborhood of London and other large cities, it is easy to pick out those roads which carry motor-bus traffic, as they invariably show the kind of wave formation above described. On water-bound macadam roads it is no uncommon thing to find considerable stretches in which the difference in level between the wave crests and troughs amounts to 4 in and over. This wave formation is noticeable in rock and sheet-asphalt pavements laid on 9 in of concrete as well as on country roads covered with sheet-asphalt, tarred slag, bituminous concrete or bituminous macadam. Generally speaking, the wave formation in sheet or rock asphalt pavements laid on concrete foundations, while noticeable, is not excessive, whereas in bituminous surfaces on inferior macadam foundations it is one of the primary causes of disintegration. The consistency of the bituminous binder used in these English roads is on the average somewhat harder than that used in the United States and there are no long hot periods to soften them up such as are frequent here. In their very moist climate it has been found that a harder bitumen adheres more tenaciously to the mineral aggregate and is less affected by water action. It is fair to assume, therefore, that their road surfaces are at least no more plastic than ours and personal examination showed that in the majority of them the bonding qualities of the bitumen had not been weakened by water action and that the grading of the mineral aggregate was normal. It is believed that much of this could be avoided by having longer and more flexible springs on vehicles of this type, thus greatly lessening the road shock.

"Slow moving, heavily loaded vehicles are much more prone to cause displacement and wave formation than are the lighter type of vehicles moving at a speed of from 15 to 25 miles per hr. This was clearly shown by a 60-ft street in one of our eastern cities, which was paved with a bituminous concrete mixture containing more stone than the average Topeka mixture. The foundation was 5 in of concrete and the average grade about 3%. A trolley line in the center of the street sharply divided

the moving traffic. The traffic up-hill was composed largely of slow-moving, loaded, 3 to 4-ton horse-drawn vehicles and a few motor trucks, whereas on the down grade it was confined to light delivery wagons and empty trucks, but the number of vehicles on each side was about equal. The pavement on the up-hill side very soon developed wave formation to such an extent as to require a large amount of resurfacing, whereas that on the down-hill side gave satisfactory service for a long period with practically no wave formation. Both sides were laid with the same mixture and at the same time. The concrete in many places was defective and at these points the wave formation was most marked."

Theory of Cause of Waves in Bituminous Pavements. Hempelman (85) states that in St. Louis there has been recorded on the surface of bituminous pavements a temperature of 142° F and in less than 6 months a temperature of 4° below zero. It was thought that there might be a sufficient difference in temperature between successive imaginary layers, meaning at different depths from the surface in contact with the wheels of the passing vehicle, as to result in a material change in the consistency of the asphaltic or tar binding cement for these various depths under the climatic conditions such as obtain in Missouri and other states of the central Mississippi valley. It is not uncommon in this section to experience a dry, hot spell of from 5 to 8 weeks, during which period the atmospheric temperature may not fall below 80°. In other words, there is not a marked cooling of the atmosphere with sundown, and, hence, the pavements do not cool to the same extent for their entire depth, as in other localities, all of which means the pavement tends to remain soft or plastic, due to the softening or change in consistency of the bituminous cement.

The temperatures recorded in Table VII were obtained by drilling holes into the pavement, inserting thermometers to the depths indicated, and packing the spaces about the thermometers with a mixture of sand and a heavy flux oil.

Table VII.—Temperatures at Different Depths in a Bitulithic Pavement on Sept. 12, 1912

Time	Air: °F	1 In: °F	1½ In: °F	2 In: °F	2½ In: °F
9.30 A.M.	90.0	94.0	91.5	90.0	88.0
10.00 A.M.	93.0	97.5	94.2	91.8	89.5
10.30 A.M.	95.4	101.5	97.5	94.8	91.8
11.00 A.M.	99.0	104.0	99.2	96.0	93.5
11.30 A.M.	102.0	109.0	104.5	100.5	97.5
12.00 N.	104.3	111.2	106.8	103.0	100.2
12.30 P.M.	104.0	113.0	108.5	105.0	102.2
1.00 P.M.	103.0	113.8	110.0	107.0	104.2
1.30 P.M.	104.0	114.5	111.0	108.0	106.0
2.00 P.M.	104.0	114.0	111.0	109.0	107.0
2.30 P.M.	103.0	113.2	110.6	109.0	107.3
3.00 P.M.	100.0	109.2	107.6	107.5	106.5
3.30 P.M.	98.5	106.0	105.0	105.5	105.0
4.00 P.M.	96.0	103.5	102.8	104.0	103.5
4.45 P.M.	93.0	101.0	100.8	102.3	102.0

CONCLUSION. Hempelman concludes that with the difference in temperature for the different depths, as indicated, it would seem that the change in consistency of the asphaltic cement for these different depths might easily permit the shifting of the wearing surface material where the bituminous cement used was of a susceptible nature, that is, a material which changes decidedly in consistency for slight changes in temperature.

Causes of Failure of Bituminous Gravel Concrete Pavements by Howard (89). The practical objection to the use of gravel, as found in a bank or pit, is the lack of uniformity as stored by nature. Where poorly graded sizes have been used, voids or pockets are formed; even tho some sand, etc, is mixed with the gravel. Rain and the elements of weather, the worst enemies of roads, cause water to enter these voids and disintegrate the roads, aided by freezing and expanding. The weather, and especially

contraction in cold weather, causes many minute cracks; and traffic disengages the gravel and ravels the road surface. Other failures occur when too large sizes of gravel are used, where stones are of greater or almost as great diameter as the thickness of the wearing surface. If water-soluble cementitious clay is present on the gravel, then it remains as a film or layer, coating each particle of gravel, and thus prevents the bituminous cement from coming in contact with and adhering to the gravel. If the surface of a gravel is too smooth and polished, bituminous cements sometimes fail to adhere.

"The bituminous gravel concrete roads or pavements which have succeeded in a few parts of the United States are those containing very hard and durable gravel, having surfaces to which bitumen can adhere, and of such expressly graded sizes that such gravel can be combined with some sand and suitable finer filler to make a dense mineral mass with a low percent of voids."

23. Methods of Maintenance

Repairs to Seal Coats. Due to ordinary wear under traffic, the seal coat of a bituminous concrete pavement usually requires repairing independent of repairs to the bituminous concrete of the wearing course. Wear of seal coats is generally characterized by the development of small areas of surface devoid of a thin coat of bituminous cement. Similar bare spots will be found early in the life of some pavements due to lack of uniformity in the distribution of the bituminous cement for the seal coat during the construction of the pavement. Such areas may be satisfactorily repaired by the following method: Thoroly clean the exposed surface of the wearing course of bituminous concrete, when dry, by first brushing with stiff brooms and then removing the fine dust by brushing with fine fiber brooms, such as those made from bass wood; apply with a broom or brush the hot bituminous cement, using from 1/8 to 1/2 gal per sq yd, dependent upon the porosity of the bituminous concrete surface and the kind of bituminous cement used; for close mosaic surfaces, cover the bituminous cement with a thin dressing of Portland cement, and for porous surfaces use a covering of grit, preferably stone chips free from dust.

Long narrow strips of exposed surface may be repaired by using a conical pouring can, such as is used for filling joints of block pavements with bituminous cement. By brushing or squeegeeing the stream of bituminous cement thus distributed, a satisfactory coating of bituminous cement may be secured. For large areas requiring renewal of the seal coat, pouring pots or hand-drawn distributors from which the bituminous cement flows in the form of a sheet, or hand-drawn pressure distributors may be efficiently used. Wide squeegees or brushes should be used immediately following the application of the bituminous cement to insure uniform distribution. For large areas it is usually better to use stone chips rather than Portland cement for a dressing.

The bituminous cement used should be of the same general type as employed in construction. If tar cement was employed, a tar, which may be applied hot or cold, may be used with good results. If asphalt cement was used for the original seal coat, a cut-back asphalt or an asphalt cement may be used. The penetration of the asphalt cement under a load of 100 g for 5 sec at 25° C (77° F) should be between 90 and 120 for oil asphalts and as high as 140 to 170 for cements similar to Bermudez asphalt cement. It will not be difficult to secure a satisfactory bond between an asphalt cement and the surface of the wearing course provided the surface is dry and the work is done when the air temperature is not less than about 20° C (68°F).

Renewal of Seal Coats. The details of the methods outlined for repair-

ing seal coats apply with equal force to the renewal of seal coats. On sections over 2000 ft in length, a different plant equipment should be used. Altho by using pouring cans and hand-drawn distributors satisfactory results may be secured, it usually will be more economical to use large pressure distributors, horse-sweepers for the first brushing and, in some cases, horse-drawn or motor mechanical stone chip or sand spreaders.

Patching Wearing Course by the Layer Method. The repairs of small areas of the wearing course, varying in character from depressions of ½ in in depth to patches having depths equal to the thickness of the bituminous concrete, have been made by the layer method, especially in the case of Class A pavements. This method consists of coating the cleaned depression with bituminous cement, adding a layer of road metal and repeating the operation until the depression is filled. Altho satisfactory results have been obtained under expert supervision and other favorable conditions, usually there results an unstable patch which has been rapidly displaced if the pavement is subjected to heavy traffic, especially one including horse-drawn or motor trucks.

Patching Wearing Course with Cold Mixtures. Satisfactory results have been obtained by patching bituminous concrete pavements using mixtures of unheated road metal and either an unheated cut-back asphalt or a tar cement. Due to the crude manner of mixing employed, this method has been most satisfactorily used with bituminous concrete of Class A. The details of mixing and laying and the kind of material used in this method of patching are well covered by the following specifications of the Ohio State Highway Dept.

Method of Patching. "The depression or area to be patched shall be thoroly cleaned of all loose, matted dirt or foreign material, and swept clean of all dust. When clean and dry, the depression shall be painted with the same kind of bituminous material as is used in preparing the bituminous concrete. When the depression is deeper than 3 in, it shall be first filled to within 2 in of the road surface with No. 2 stone (see Sect. 15, Art. 11), which shall be thoroly tamped in place. The depression shall then be filled with bituminous concrete prepared as described below, in sufficient quantity to fill the depression to the level of the surface of the surrounding pavement after the bituminous concrete is thoroly compacted. The patch shall be covered with sufficient No. 6 grit (see Sect. 15, Art. 11) to prevent the bituminous material from sticking to the wheels of the roller, and then thoroly compacted by rolling. The surface shall be covered with No. 6 grit, or clean, coarse sand, to protect the patch while setting up.

"**The Bituminous Concrete** shall be prepared by one of the two following methods, using the same kind of aggregate as was used in the original construction of the road; also bituminous material same as original construction, that is, either tar or asphalt.

1. When an asphalt-bound road is to be patched, the bituminous concrete shall consist of a mixture of bituminous material A.C.B. and No. 4 size stone or slag (see Sect. 15, Art. 11) in the proportion of 1¼ gal of A.C.B. to 1 cu ft of aggregate. The aggregates shall be thoroly and uniformly mixed on a tight platform by hand methods or in a concrete mixer, until each particle of stone is completely coated with the bituminous material. After mixing, the bituminous concrete shall be stored, where it will be free from dust or dirt for 24 hr, or until the bituminous material stiffens sufficiently to bind when the patch is made. When required by the commissioner, a small amount of clean, coarse sand shall be added to the aggregate.

2. When a tar-bound road is to be patched, the bituminous concrete shall consist of a mixture of bituminous material T.C.B. and No. 4 size stone or slag in the proportion of ¾ to 1 gal of T.C.B. to 1 cu ft of stone. The aggregate shall be thoroly and uniformly mixed on a tight platform by hand methods or in a concrete mixer, until each particle of stone is completely coated with the bituminous material. After mixing, the bituminous concrete shall be stored, where it will be free from dust or dirt, for several days until the bituminous mixture stiffens sufficiently to bind when the patch is made.

"In either of the above methods the stone shall be dry when mixed with the bituminous material and neither stone or bituminous material shall have a temperature of less than 10° C (50° F) when mixed together.

"**Asphalt Cut-Back.** The material shall be a cut-back asphalt prepared in a still by compounding 35% of a distillate meeting the following specifications for distillate and 65% or an asphalt meeting the requirements as specified for Bituminous Material A-2, Sec. 6.2.

"The distillate shall have a specific gravity of not less than 0.736 nor greater than 0.765 at 25° C (77° F) and shall have an end point of distillation of 170° C (338° F).

"The cut-back asphalt shall conform to the following tests:

1. It shall be homogeneous in character.
2. It shall have a specific gravity of not less than 0.90 at 25° C (77° F).
3. When 20 g of the material are heated for 5 hr in a cylindrical tin dish approximately 2½ in in diameter by ¾ in high at a temperature of 163° C (325° F) the loss in weight shall be between 35% and 40%. The penetration, 5 sec, 25° C (77° F), No. 2 needle, 100 g weight, of the residue shall be not less than 3.5 mm nor more than 6.0 mm.
4. The specific viscosity as determined on the first 50 cu cm by means of an Engler viscosimeter at 25° C (77° F) shall be not less than 25 nor more than 35.
5. When distilled in an Engler distilling flask to 170° C (338° F) the material shall yield a distillate having a gravity of not less than 0.736 nor greater than 0.765 at 25° C (77° F).
6. The residue from the above distillation shall have a ductility, Dow mold, of not less than 30 cm.

"**Tar for Cold Application.** Bituminous material T.C.B. shall meet the following requirements:

1. It shall have a specific gravity of not less than 1.15 nor more than 1.20 at 25° C (77° F).
2. On extraction with carbon disulphide it shall contain not more than 15% nor less than 8% free carbon.
3. Upon ignition it shall show not over 0.5% inorganic residue.
4. When 240 cu cm of the tar are heated in an Engler viscosimeter to 50° C (122° F) and maintained at this temperature for at least 3 min, the first 50 cu cm which flow thru the aperture shall show a specific viscosity of not less than 3 nor more than 15.
5. When distilled by the method proposed by the Am. Soc. Test. Mat. not less than 15% shall distill below 235° C (455° F); not more than 35% shall distill below 300° C (572° F). The residue from the foregoing distillation shall have a melting point not greater than 75° C (167° F) by the cube method.
6. The tar shall be free from water.
7. All bituminous material used in a given construction shall be uniform in character, appearance and viscosity."

Plant Operation in Ohio, by Hinkle (37). "A very convenient way to handle work of this kind is to do all the mixing and storing of materials at one point, near the middle of the section of road to be repaired, and then use a wagon whose box is divided into compartments to hold a barrel of tar or asphalt for painting the surface, the bituminous concrete, sand for cover, etc, and have the wagon follow along as the work progresses. A central station, where the bituminous concrete may be mixed by machine, may be provided and all the bituminous concrete required for a district mixed in one place. The bituminous concrete can be hauled in trucks from the central plant and delivered to the repair crews working at various places on the road. While such a stationary plant is very practical under some conditions, it would not be practical where but a small amount of the mixture is wanted as here the mixing would likely be done by hand to better advantage on the road. Also where a large amount of the concrete is wanted on one road, the plant should be located on the road or at the delivery station of the materials for that road."

Penn. State Highway Dept. Practice by Biles (18), giving reasons for, and methods of, repairing.

"CRACKING OF THE SURFACE is one of the greatest as well as one of the earliest defects that may develop in bituminous pavements. This may be due to one cause or a combination of several causes. Frequent cases are noted in bituminous wearing surfaces which, altho apparently satisfactory mixtures in all other respects, contract

as the base contracts and crack open at exactly the same point as the foundation. Again, cases are noticed of otherwise satisfactory pavements which crack because of their failure to receive the amount of traffic necessary to give the pavement its full compression or to iron out and close up the surface after low temperatures have made it tend to open up by stretching the bituminous binder. A condition of the sort last described, however, may have been hastened considerably or even caused directly by what might be called improper design of the pavement in the first place. The bituminous surface mixtures expected to receive heavy traffic should be tough and fairly hard in order to resist displacement. Those designed for light traffic should be softer and more yielding, and this is accomplished by using a softer bitumen, that is, one of a higher penetration. Failure to do so means that as the pieces of mineral aggregate contract or shrink in volume during cold weather, they exert a spreading force in the surrounding bitumen, which it cannot withstand because of its lack of light fluxing oils and corresponding ductility or ability to stretch; in other words, pavements containing hard or non-ductile bituminous material will have a greater tendency to crack in cold weather. Similar results and even general disintegration of the wearing surface may have been produced by too little bitumen in the mixture, since this is largely a measure of the life and elasticity of the pavement, and similarly, overheated mixtures suffer a hardening and reduction of bonding power of the bitumen, with consequent tendency to crack and wear. Aside from faulty drainage, poorly proportioned mixtures and unsuitable ingredients contribute largely to the failures in this type of pavement. A cracked bituminous surface, unless the cracks are caused by some serious form of disintegration in the pavement, can be repaired by cleaning the cracks out thoroly and pouring them full of either a hot or cold bituminous material of the proper grade, and thereafter tamping or wedging stone chips into the crack, thoroly sealing it. If the crack is wide enough and the edges have crumbled or broken off, they should be cut down evenly and the opening filled and tamped with a mixture of the bituminous cement and stone chips in a proportion of 1 part bituminous cement to 9 parts chips, in sufficient quantity to insure complete closure.

"Pot-Holes and Depressions can be repaired by cutting out the affected areas down to the foundation and replacing with new mixture. The character of the bituminous material to use depends entirely upon the conditions in each case. Unless the repair work is extensive, it is not deemed advisable to use hot bituminous compounds in this work, not only from the standpoint of economy, but from a point of convenience as well. Small repairs in the proper season can be handled economically and efficiently with cold bituminous cement, and if the proper mixture is used in the regular working season excellent results can be obtained. It is conceded that hot bituminous repairs are not generally satisfactory when made at low temperatures, but in some places the avoidance of this practice has been carried almost to a fault. As an example, in some of the larger municipalities where defects have developed in the surface during the winter months, the affected portions have been removed and repaired with brick or stone block. This method is not only objectionable on account of the annoyance to traffic but, when the regular season for repairs arrives, it is usually found that additional work is required, occasioned thru the inequality of the surface. It has been stated by some of the advocates of this method that it is an assurance that the affected portions will not be overlooked when the repair work is taken up in the spring. It has been demonstrated, however, that where conditions are so acute that this method is warranted, there is justification for making special arrangement for preparing and placing a suitable bituminous mixture which will be more satisfactory in the interim and, tho probably not a complete success, will offer as good, if not better, opportunities to correct later than the first method which seems only to be justified when repairing cuts made in the pavements by public service corporations in the winter season.

Deterioration of Pavement Edges. "The wearing and deterioration along the edges of bituminous pavements where there is no header, is responsible for one of the most troublesome and expensive forms of repairs to roads of this type. The traffic continually irons out the surface along the edges and this spreading or flattening out produces a feather edge along the side. The moisture and foreign material tracked on from the shoulder soon attack the bituminous material and result in the crumbling or breaking away of the surface which occasions extensive repairs. This condition is more pronounced when the material in the shoulders is of a non-porous nature or is

poorly drained. In the repairs to the edges of a bituminous pavement not confined by headers, the first and most essential thing to do is to correct the cause, if possible. If the drainage of the shoulders or base is faulty, this should be taken into consideration first and ample provision made therefor. On shoulders which are composed of non-porous material, it is advisable to cut scuppers or small surface ditches at intervals of approximately 20 ft along the road and, in addition to this, the material immediately along the edge of the pavement should be replaced for a depth of a few inches with broken stone or gravel tamped into place to produce a more stable buttress for the new bituminous material. The patches should be made by removing the affected area and replacing with new mixture. Successful repairs should neither be above nor below the surrounding surface when finally compacted.

PLANT EQUIPMENT. "In municipalities where there is enough yardage to warrant a central mixing plant, this is the most satisfactory method of handling bituminous repairs. With every facility at hand to compound the mixture properly, more uniformity is assured and much of the personal equation resulting from separate organizations is eliminated. There are localities where possibly small portable mixing plants would meet the requirements and give satisfactory results. However, under ordinary conditions, the problem is generally a small town with probably several short streets or some other unit, such as a county or state, with continuous stretches of miles of interurban bituminous pavements or highways. In either case, it means one outfit or a number of outfits performing the repair work, which conditions give strength to the demand for simple and efficient methods. With trained men, good hot bituminous mixtures have been prepared by hand, but considering the chances taken in overheating the material, the careless proportioning and mixing, and the extra expense in connection with the handling of the equipment, etc, this method is not justified. The cold bituminous mixture with the proper material is the most economical and foolproof method for ordinary repairs. The material can be mixed on a regular mixing board, stock prepared for future use, if need be, and stored at convenient intervals along the road and, aside from the small tools, such as shovels, rakes and tampers, no other equipment is absolutely necessary. Repairs have been made with cold bituminous mixtures on extremely heavily traveled roads that are in excellent condition after four seasons of wear."

U. S. O. P. R. 1918 Specifications for Tar for Cold Patching, and Recommendations for Use.

"GENERAL. The tar shall be homogeneous.

"PHYSICAL AND CHEMICAL PROPERTIES. It shall meet the following requirements:

1. Specific gravity 25°/25° C (77°/77° F), 1.100 to 1.200;
2. Specific viscosity at 40° C (104° F), 40 to 70;
3. Total distillate by weight:
   To 170° C (338° F), not less than 2.0%;
   To 270° C (518° F), 15 to 25%;
   To 300° C (572° F), not more than 30.0%;
4. Total bitumen, soluble in carbon disulphide, not less than 80%.

"METHODS OF TESTING. Tests of the physical and chemical properties of the tar shall be made in accordance with the following methods:

1. Specific gravity: Bul. U. S. Dept. Agr., 314, p. 4.
2. Specific viscosity, on first 50 cu cm: Bul. U. S. Dept. Agr., 314, p. 7.
3. Distillation test: Bul. A. S. T. M. Standard Test D 20–16.
4. Total bitumen: Bul. U. S. Dept. Agr., 314, p. 25.

"NOTES: This specification provides for a material to be used in the repair of surface breaks, holes and depressions in bituminous bound and surface treated roads. It is intended to cover preparations consisting of gas-house, coke-oven or water-gas tars or pitches which have been rendered sufficiently fluid by the addition of distillates to enable them to be handled without heating.

"METHODS OF PATCHING. For surface breaks and shallow depressions or those which in general do not exceed ½ in in depth, a patch may be made by painting the bottom of the depression with the tar, and scattering over it a sufficient amount of stone chips to fill the depression. In repairing deeper depressions and holes, the old material should be removed to yield a clean bottom. The sides of the hole should be cut approximately vertical. A mixture of graded broken stone with just a sufficient amount

of tar to thoroly coat each particle should be prepared, and firmly tamped into the hole to form a neat patch in the surface. A thin layer of sand or screenings over the patch will prevent it from picking up under traffic."

Patching and Reconstructing Wearing Course with Hot Mixtures. The most efficient method of repairing bituminous concrete wearing courses is to use the same kind of mineral aggregate and the same kind of bituminous cement that was employed in the construction of the pavement. Usually, fulfilment of the above requirements necessitates the heating of the mineral aggregate as well as the bituminous cement. By this method of repairing, maximum homogeneity of the wearing course is obtained and sufficient stability is secured to prevent the newly laid bituminous concrete from being displaced by traffic. The efficiency of this system depends upon the kind of plant equipment and repair organization, and the location and character of the bituminous concrete pavements in a given system.

THE PATROL SYSTEM of maintenance generally is not applicable to this method of repairing due to the plant equipment required to manufacture suitable bituminous concrete.

THE MOBILE GANG SYSTEM has worked out satisfactorily by using either a stationary or portable plant. Under such conditions as exist in municipalities or in highway systems outside of urban districts such as the Ashokan Reservoir Division of the Board of the Water Supply of New York City, where 32 miles of one type of bituminous concrete has been constructed, the utilization of a stationary mixing plant and motor trucks for the transportation of the hot mix is justifiable on economic grounds. When, however, the bituminous concrete pavements are widely scattered thruout a county or state system of highways, the portable plant will prove economical.

The following plant equipment would prove satisfactory for the maintenance of 50 miles of bituminous macadam and bituminous concrete pavements well distributed over an area of, say, 2000 sq miles. The equipment should include a motor truck and a trailer. The truck would be used for transportation of broken stone, sand, cement, fuel, bituminous materials and small tools and accessories. A trailer should be permanently equipped with a small mixer, drier, and melting kettles. In many cases the following accessories could be used efficiently: A hand-drawn gravity distributor, pouring cans which distribute the material in the form of a sheet, conical pouring cans such as are used for the application of bituminous fillers, coarse fiber and bass fiber brooms, a heavy hand-drawn roller, tampers, smoothing irons, squeegees, a large hand power bellows, a small surface heater, and other small tools, such as shovels and picks. If large areas are to be repaired, a horse-drawn sweeper, a small pressure distributor, and a tandem roller should be included in the equipment.

English Patching Methods with Plant Mixed Bituminous Concrete by Hooley (38b). "Observation must be made after rain where holes or depressions appear and water stands. Each lengthman must ascertain to what extent water stands, and must then, by scratching with a strong nail around the edge of the water puddle, mark how much excavation will be necessary to raise the depression up to the adjoining surface. This mark must, directly the road is again dry, be marked deeper by a pick if the work of patching cannot be at once undertaken. When the work of patching is commenced, each lengthman must have a sufficient quantity of 1½-in and ⅝-in tarred material at hand to deal with the patch, and on no account must one patch be commenced before the other is finished and the road levelled. He must be provided with two sharp picks, a coarse and a fine brush, an 8-lb rammer, and a straight-edge.

"The top layer of material within the marked area must be thoroly excavated to a depth of slightly more than 1½ in, or a little deeper than the depression; the bottom must be left as rough by picking as possible. Every trace of loose or wet material must

be swept out with the coarse and fine brushes, so that a rough, clean base is presented with the edges shaped to a sharp arris to the remaining road surface, and, if possible, slightly deeper on the outside edge than the center of the patch. The arris edge must then be treated with a layer of ⅝-in and the center with 1½-in tarred material, every piece of the material being made to touch. Any overplus of ⅝-in must be swept towards the center and every crevice filled with ⅝-in. The whole must then be well and regularly rammed until perfectly level. This level will at once be found by the application of the straight-edge. On no account must any feather-edge be left. The patch must be in the hole, and on no account be made to overlap, for if overlapping takes place, the edges will at once break away and fret."

Maintenance of Asphalt Block Pavements by Morrison (48).

"There are three principal things to be guarded against in the maintenance and repair of asphalt block pavements: (1) Allowing small defects to go unrepaired until they grow into actual holes in the wearing surface; (2) making an incomplete, and therefore ineffectual, repair by simply plugging the hole and failing to make a repair of sufficient area to restore the surface of the pavement to its original grade and contour; (3) neglecting or failing to utilize the old blocks in a proper and effective manner.

"Blocks that are ten or more years old are generally hard and dry, the reason for which will be described later, and in taking up and relaying them the edges and corners are liable to be damaged. If the joints are simply filled with sand, the edges crumble under traffic, producing a rough and unsightly surface. The only proper method of treating the joints is by the use of an asphaltic filler. Where the joints are larger or the edges and corners badly chipped, they should be filled with dry trap rock grits before pouring the asphaltic filler.

"The joints should be made water-tight. The asphaltic filler is spread out by traffic, thus protecting the surface of the block as well as the joint. The importance of treating the joints in this manner cannot be overstated. Such a repair results in a smooth surface, which under the action of traffic renders the patch indistinguishable in a very short time, whereas a patch made with the same blocks, with sand-filled joints, generally produces a rough surface with a percentage of bad joints which are subject to deterioration under traffic during the winter. The cost of applying the asphalt filler, which will be described later, is small and insignificant when balanced against the benefits accruing from it. In making repairs to asphalt block pavements, the old blocks should be used to the utmost extent, and the new ones should be placed in continuous areas by themselves. The old blocks which are of the same formula, age and wearing quality will thus be brought together, and from the new blocks, laid by themselves, will be derived their utmost serviceability. Practically every whole block can be salvaged and efficiently used. This is true even where the blocks have one surface badly mutilated and are of unequal thickness, since the bad and irregular surface can be bedded in the mortar and the smooth surface of the blocks exposed to traffic.

"The brittle condition of the old blocks (due to the use of a very hard asphalt cement, which gradually grew harder with the lapse of years as the volatile matter in the flux oil evaporated) led to the inauguration of a series of experiments to determine a satisfactory and economical method of surface treatment which would soften the hard asphaltic cement and prevent the chipping of the blocks in winter. The method which produces the desired result is to dissolve a heavy bituminous oil in a volatile solvent and apply it to the surface of the old blocks in the form of a thin wash or paint coat, given one or more applications, as considered necessary. The solvent penetrates a considerable distance into the blocks and then evaporates, leaving a coating of heavy stable bitumen, which mixes perfectly with the old asphalt, softening and giving it new life while producing a malleable surface on the old blocks very similar to that produced by the formulas now used in the manufacture of new blocks. After the application of the paint coat the entire surface of the pavement should be covered with a very thin layer of dry, fine trap rock screenings, passing a ⅛-in screen; or any clean dry sand will answer the purpose if trap rock is not available. The fine trap rock, sand and dust serve the double purpose of preventing the oil from being picked up by the shoes of pedestrians and tires of vehicles, and, what is more important, cause the oil to be ground by traffic into the joints and inequalities of the surface. Where the joints are only slightly broken down this simple application is all that is needed to

restore the surface of an old asphalt block pavement to a satisfactory condition. The cost of this surface treatment when applied to large areas ranges from 2 to 4 cents per sq yd."

Brooklyn, N. Y., 1914 Specifications for Repair of Asphalt Block Pavements (48).

"The work shall consist of the removal of the present asphalt block pavement and mortar bed; the repair of the present concrete foundation; the repaving of the roadway with asphalt blocks made up in part by new blocks and in part by old blocks taken from the present pavement; the treatment of the surface of the old blocks and all work incidental thereto; all in accordance with the plans and specifications on file in the Bureau of Highways, and over such areas as the engineer may direct.

"The thickness of the mortar bed used under the culled blocks which are repaved over the above areas shall be approximately ½ in, but sufficient to bring the upper surface of the relaid blocks to an even grade with the adjacent pavement surface.

"The asphalt blocks forming the present pavement, as taken from the street, shall be carefully culled and blocks which show a depth of 1½ in or over and are otherwise suitable shall be piled separately and used for repaving. The old asphalt blocks which can be used again shall be used to repave such areas as the engineer may direct. In addition, the contractor shall furnish and lay, as directed by the engineer, new asphalt blocks, which shall conform in all particulars with the current asphalt block specifications of the Bureau of Highways, Borough of Brooklyn, which, so far as they apply, are made a part of this specification.

"The surface of the present pavement which has not been disturbed, and those areas which have been repaved with blocks culled from the present pavement, shall be thoroly broomed over with steel brooms and the joints cleaned and freed from all dirt and loose material. Into the joints between the blocks shall be poured quartz gravel, crushed granite or trap rock, which shall be clean, approximately cubical, free from all foreign materials and shall pass a ¼-in mesh sieve and be retained by a 20-mesh sieve. It shall be artificially heated and dried in proper appliances placed near the work before being placed in the joints, if required by the engineer.

"Immediately following the application of the gravel, the joints shall be poured with an asphaltic cement conforming to the following requirements: The block filler shall be a blown asphaltic oil product, or a residual asphalt: (1) It shall contain not less than 99% of bitumen soluble in carbon disulphide; (2) it shall contain not less than 98.5% of total bitumen soluble in carbon tetrachloride; (3) it shall have a penetration at 25° C (77° F), under a load of 100 g, for 5 sec, of not less than 55 nor more 75; (4) it shall have a penetration at 0° C (32° F), under a load of 200 g, for 60 sec, of not less than 25; (5) it shall have a penetration at 46° C (115° F) under a load of 50 g, for 5 sec, of not more than 200; (6) it shall have a ductility at 25° C (77° F) of not less than 5 nor more than 25 cm.

NOTES: "When the specifications were prepared it was expected that the work would be done in midsummer and that the treatment of the joints, as previously described, would be sufficient for their protection, and that the summer traffic would distribute the asphaltic filler over the surface of the blocks sufficiently to protect them against any tendency to pit or rough up during the succeeding winter. This treatment would undoubtedly have been sufficient if the work had been done in midsummer, but as it was actually done in the cold weather of late November it was considered advisable to add to the treatment described in the specifications a surface treatment of the entire area of old blocks. This consisted of a paint coat composed of crude oil and a heavy asphaltic maltha of about 12° B, mixed half and half, applied hot and squeegeed over the surface, followed by a thoro sprinkling with fine trap rock grits and dust passing a 20-mesh sieve."

Maintenance Record of Class A Bituminous Concrete Pavements in Jamaica, N. Y. (67b).

This experimental road, 25 ft wide, was built in Aug. and Sept., 1911. The work consisted in resurfacing a 2000-ft length of badly worn, water-bound macadam pavement on Hillside Ave. Before the experimental work was begun the old macadam surface was scarified and rebuilt to a crown of ⅜ in per ft by addition of material and rolling. The aggregates used in all the experiments were clean, crushed trap rock, screened according to the following grades: ¾-in stone, passing 1¼-in circular opening and retained on ⅝-in opening; ⅜-in stone screenings, from which dust had been removed.

A Traffic Census in 1911 showed an average of 1493 vehicles per day of 24 hr, 25% of which was horse-drawn wagons and motor trucks. On Sat., May 18, Sun., May 19, and Mon., May 20, 1912, the traffic was 2995, 5199 and 1795 vehicles, respectively; the average number of horse-drawn wagons and motor trucks on May 18 and 20 being 460.

Asphaltic Concrete constructed with fluxed native asphalt used in the mix and for the seal coat. Details of construction were as follows: Compacted depth 2 in; proportions, 7.5 cu ft of ¾-in dried stone to 5.5 gal of A. C. heated to 167° C (340° F); surface finished with seal coat of A. C. and ½-in stone.

Record of condition and maintenance on dates given. May, 1912, excellent condition, except at station 5 + 00, a slight depression due to wear; repaired by applying an oil-asphalt seal coat. June, 1913, slightly wavy, otherwise in excellent condition. Jan., 1915, all in good condition, except in places where house sewer connections were made. Jan., 1916, same as when last inspected.

Tar Concrete constructed with refined coal tar used in the mix. Details of construction were as follows: Proportions, 10 cu ft ¾-in dried stone to 7 gal tar; for the seal coat, coal tar was used for the first 150 ft, oil-asphalt for the second 150 ft.

Record of condition and maintenance on dates given. May, 1912, seal coat of oil-asphalt in good condition; seal coat of refined coal tar entirely worn off; new seal coat of light coal tar at the rate of 0.28 gal per sq yd applied from station 8+00 to station 8+70 and from station 8+70 to station 9+50, seal coat of tar-asphalt preparation applied. June, 1913, slightly wavy; otherwise in excellent condition. Jan., 1915, section in excellent condition, except for wavy surface in places and for a few small spots where seal coat was worn off. Jan., 1916, wavy on sides; center in good condition; on south side surface crumbling where seal coat has been worn off.

Excerpt from report of committee of supervising engineers, covering investigations made in March, 1916. "The east end, which carries an asphalt seal coat, is in excellent condition. The surface is much smoother than where a tar coat has been applied, and the seal coat is still intact. At the present time this portion of the experiment is probably the most satisfactory from the standpoint of serviceability that has developed in connection with the entire series of experiments."

SHEET-ASPHALT AND ROCK ASPHALT PAVEMENTS

BY

FRANCIS P. SMITH

CONSULTING CHEMICAL AND PAVING ENGINEER, NEW YORK CITY

SHEET-ASPHALT PAVEMENTS

ROCK ASPHALT PAVEMENTS

SHEET-ASPHALT PAVEMENTS

GENERAL DATA

1. Description and Historical Development

Description. Sheet-asphalt pavements differ broadly from other types of bituminous pavements by having a wearing surface, the mineral aggregate of which contains no particles which would be retained on a ¼-in screen. As usually laid they consist of two distinct courses laid on a foundation of old macadam, bituminous concrete or Portland cement-concrete.

1. Binder course: Composed of asphalt cement, broken stone and usually sand. Sometimes a paint coat composed of asphalt dissolved in naphtha is applied to the surface of the concrete foundation and the binder course is omitted.
2. Wearing course: Composed of sand, filler and asphalt cement.

Historical Development. Mixtures of coal tar with sand, gravel, broken stone, ashes, and materials of a similar nature were employed in the United States prior to 1865 on sidewalks and cross-walks. They undoubtedly were the first step in the development of the modern sheet-asphalt pavement, as the general principle involved, of mixing hot sand with a bituminous cementing material, is substantially the same in both cases. This is also true of the method of laying. A mixture of this kind was laid on one of the highways in Prospect Park, Brooklyn, N. Y., in 1867 and was so successful that a similar pavement was put down the following year on Diamond St. in Brooklyn. The foundation of this pavement was 5 in thick and was composed of 2-in broken stone, sand, coal ashes and tar. The wearing surface was of similar composition except that the stone used in it was not larger than 1 in in its greatest dimension. This is probably the first street in the United States which can be considered as having had a bituminous pavement. Shortly after 1870 a number of coal-tar pavements were laid in Washington, D. C. The base used was broken stone, 4 to 6 in in thickness, which was cemented together with coal tar. This base was covered with a binder course averaging about 1 in in thickness and composed of gravel, fine broken stone and coal tar. Generally speaking, the foundation and binder course were substantially the same in all cases but the wearing courses differed considerably and were laid under numerous patents. Some of these pavements were very good and some were very bad but even the best of them became very soft in summer and could not be regarded as generally satisfactory, and where the traffic was at all considerable their cost of maintenance was high. This appears to be the first recorded development of the modern binder course. In 1870, E. J. deSmedt, who was familiar with the art of laying bituminous rock pavements as developed in Paris, laid an asphalt sand mixture in front of the city hall in Newark, N. J., which proved successful. This was undoubtedly the first asphalt pavement laid in the United States, altho its exact composition is in doubt. It was followed by similar pavements in New York City and Philadelphia. As a result of these, Pennsylvania Ave. in Washington, D. C., was paved with an asphalt sand mixture in 1877. The use in Washington of this type of pavement rapidly increased and other asphalts began to be used for the same purpose and from this beginning the use of sheet-asphalt pavements rapidly developed thruout the country. It was not until many years later that sheet-asphalt pavements were laid in England and on the Continent.

2. Characteristics

Sheet-asphalt pavements are smooth, non-productive of dust, almost noiseless, waterproof, non-absorbent and easy to clean. They are capable of sustaining very heavy traffic and also last well under light traffic. They are therefore well adapted for business and residence streets and the facility with which they may be kept clean makes them especially desirable in tenement districts. They are easy to repair and offer but slight resistance to traffic. They are somewhat softer in summer than in winter but when properly laid never become too soft for use even in the hottest weather. When dry and clean they are not slippery and their slipperiness in moist or drizzly weather is largely due to the presence of a thin film of mud caused by the collection of street detritus, and this can be greatly reduced by washing or keeping them clean. For this reason they are less slippery in a heavy rain than in a drizzle. Horses accustomed to granite block pavements instinctively put their hoofs down and slide them until they obtain a foothold in the crevices of the pavement. As there are no such crevices in a sheet-asphalt pavement, it takes a little time for them to become accustomed to it but they soon learn to adapt themselves to a smooth surface.

While, as previously stated, sheet-asphalt will sustain a very heavy traffic, this statement applies more especially to a traffic largely composed of quick moving, light to medium loaded vehicles, such, for instance, as prevails on Fifth Ave., New York City. It is not the most suitable type of pavement for a very dense, slow moving, heavily loaded traffic. Wood block and granite block will outlast it under these conditions. It will not give satisfaction where there is practically a total absence of traffic, as it then is liable to develop cracks, apparently requiring the kneading action of traffic to equalize the stresses set up by contraction and expansion and to keep it in proper condition. It is entirely suitable, however, for traffic varying from the light delivery traffic of residence streets to the dense but quick moving traffic of Fifth Ave., New York City, or the Thames Embankment, London. Very recent figures as to the traffic on Fifth Ave. are not available, but a record taken between 33rd and 34th Sts. during the months of Nov. and Dec., 1904, shows it to be heavier than on the Thames Embankment, and is given below:

Tonnage per 11 hr	19 274.47
Average tonnage per lin ft of width per 11 hr	481.85
Average tonnage per hr	1 752.20
Average number of vehicles per 11 hr	11 787.00
Average tonnage per vehicle	1.64

On account of their smoothness, sheet-asphalt pavements are not suitable for use on excessive grades. Generally speaking, streets carrying a fair amount of traffic can be paved with asphalt if the grade does not exceed 6%. In some cases, where the traffic was very light and a smooth pavement was considered essential, it has been laid on grades running up to 10 and 12%, but this is rather exceptional. Where the traffic is heavy, a 3 to 4% grade is usually considered as the limit. In most of the largest cities of the United States the maximum grades on which this type of pavement is laid vary from 4.5 to 8%, regulated largely by the traffic and climatic conditions.

3. Foundations

As a sheet-asphalt pavement has not sufficient internal stability to permit it to bridge over depressions or soft spots and as excessive vibration will tend to produce rapid disintegration, it must be supported by a rigid and unyielding foundation of sufficient strength to carry the traffic. The character of the foundation required will depend upon the following conditions: Traffic, climate, character of subsoil and drainage. The strength of the foundation must be directly proportional to the weight of the traffic. In cold climates, where the ground freezes to a considerable depth in winter, the spring thaws produce a very unstable condition of the subsoil and the foundation in such cases must be stronger than is required in climates where there is little or no frost. A well drained sandy soil is much less affected by these temperature changes than is a heavy clayey soil. The treatment of the subsoil, therefore, is of primary importance, especially where the traffic is heavy. It should be drained and thoroly compacted by rolling to such an extent that it will be free from displacement thru settlement or frost. All soft spots should be excavated and filled with suitable material and all trenches must be thoroly backfilled. In sandy soils this may be done by the aid of water; in clayey or heavy soils they must be slowly filled and carefully tamped for each 6 in of fill. In certain localities in the northwestern portion of the United States and Canada very heavy clay soils are found. In winter these frequently develop cracks from 4 to 5 in in width and heave very badly. In such cases cross trenches should be dug every 25 or 30 ft and filled with coarse broken stone and connected with longitudinal trenches at the side of the street, similarly filled and draining to catch basins. It is inadvisable to lay concrete directly on such a soil. Sand and gravel should first be spread upon it to such a depth that when rolled it will form a layer 3 to 4 in in thickness and the concrete should be placed on this. Where the subgrade is marshy or swampy or consists of a fill made on such ground, and it is impracticable to thoroly drain it, concrete of sufficient strength must be employed to bridge over soft spots and distribute the load over as great an area as possible. Depending upon traffic, subsoil and climatic conditions, a number of different types of foundations have been successfully employed, such as old macadam; broken stone, either rolled dry or cemented together with some form of bituminous cement; old cobblestone; Belgian block or granite block pavements; old brick or asphalt block pavements; bituminous concrete; natural cement-concrete and Portland cement-concrete.

Broken Stone Foundations. Where the traffic is light, the climate mild, and the subsoil conditions favorable, old macadam roads which have been properly constructed and drained have given very excellent results as foundations. In some cases, notably the Thames Embankment in London, a foundation of this kind covered with an asphalt pavement has sufficed to carry a very heavy traffic, but its use under severe conditions is to be deprecated and more failures than successes have resulted from it. Stones screened out from an old broken stone road-bed are always well rounded on the edges, showing that they move under traffic and that a broken stone road, however good, does not form a rigid foundation. Many so-called broken stone roads have been constructed without any attention to drainage by simply dumping stone on top of old earth roads and consolidating it by traffic with little or no preliminary rolling. These should not be regarded in temperate climates as suitable foundations for any

permanent type of pavement. Where a broken stone road is used and the grade will permit, it is far better to build up depressions and reduce the crown if necessary by adding broken stone on the quarters and thoroly compressing it with a roller. Any attempt to remove portions of the surface by scarifying it will seriously disturb the bond of the broken stone and impair the consolidation and solidity resulting from years of travel.

Old Pavements of Brick, Granite, etc, should not be used as a base if, owing to height of curb or any other reason, it is necessary to reset them. In their original condition they are satisfactory where the traffic is not heavy. Relaid blocks are not rigid and have a tendency to rock and sheet-asphalt pavements laid on such foundations in New York City have rapidly disintegrated wherever they were exposed to heavy traffic. In almost every case the active centers of disintegration have been found to be directly over blocks which were not firmly bedded. If a foundation of this kind is to be used, the relaid blocks should first be subjected to travel for a considerable period of time and any blocks which do not thus become firmly bedded should be reset. Rolling and ramming them will not produce the desired results.

Cement-Concrete Foundations. Where the traffic is heavy, no base but Portland cement-concrete should be used and its thickness should depend upon local conditions. The requirements of modern traffic are constantly increasing in severity, and where a few years ago 6 in was considered ample, 9 in is in many instances now required. In London, all streets subjected to motor-bus traffic are being provided with 9-in concrete foundations, as 6-in foundations were found to shatter under traffic impact. In some cases 6 in of reinforced concrete is being tried, but this has hardly passed the experimental stage as yet. Where the traffic is comparatively light and the subsoil at all unfavorable, it is much better to use 4 or 5 in of concrete than to experiment with questionable macadam. A permanent and adequate base can always be used again when the pavement requires resurfacing, whereas any serious failure of the base requires a complete reconstruction of the street. Many authorities advocate the roughening of the upper surface of the concrete so that the pavement may key into the depressions thus formed and in this way reduce the tendency to shoving. Various methods of producing this roughened surface are employed. In some cases cross depressions are made by the use of pieces of timber embedded in the concrete while wet and subsequently removed. In other cases the concrete is not tamped sufficiently to fill all the surface voids with mortar, thus leaving a rough stone surface. Broken stone is sometimes sprinkled over the surface of the concrete just before it acquires its initial set. Special rake-like implements are also used to rake over the surface and score it before it has set. While it is true that pavements as a whole sometimes slide on a smooth base, exhibiting when taken up a slickenslide effect, it appears very questionable whether any pavement which lacks inherent stability to such an extent that it will shove up to an undesirable degree under traffic, will have its resistance to this action markedly increased by roughening the concrete which lies 3 in below its surface. A reasonably smooth concrete is favored as it tends to produce a more uniform thickness of pavement. Proper selection and grading of the mineral aggregate will prevent shoving. Where street-car rails are present in a street, they must be placed on rigid foundations and manholes and boxes must be similarly treated. Any excessive vibration in them will destroy the pavement adjacent to them and in many cases will permit the entrance of water between the pavement and the concrete. The usual

proportions for concrete vary from 1 : 2 : 5 to 1 : 3 : 6, altho with properly graded stone, such as crusher run passing a 2-in screen and retained on a ⅜-in screen, in which the voids are comparatively small in size, the proportion of stone may be increased considerably and the resulting concrete will be better and stronger in every way and will be much easier to compact by ramming and less liable to segregation. Bituminous concrete is in most cases more expensive than cement-concrete and has no great bridging strength. When used, therefore, it must be relatively thicker than would be necessary with a Portland cement-concrete and its use on unfavorable subsoils is not to be recommended.

MATERIALS

4. Sands

Essential Characteristics. Sand constitutes from 75 to 80% of a sheet-asphalt pavement and takes practically all the wear resulting from traffic. Sand for paving work, therefore, must be hard, clean grained and moderately sharp and must have a suitable mesh composition. The surfaces of the grains must be of such a character that asphalt cement will satisfactorily adhere to them. A careful examination under the microscope should therefore always be made of all sands proposed for use. This must be supplemented by a sieving test. Hardness is necessary in order that the grains may not crush to an undesirable extent under traffic. For this reason sands composed almost wholly of quartz grains must be selected. Sands composed largely of calcareous grains or grains composed of silicates are not suitable for paving purposes altho where the traffic is very light and the climatic conditions favorable and no other kinds have been available, they have been used with fairly successful results. The surfaces of the grains must be reasonably free from fine dust of such a character that it will bake on them when heated and prevent the asphalt cement from adhering to them with the requisite tenacity. Sharpness is essential in order that the grains may key together to such an extent as to offer strong resistance to the shoving action of traffic. A sand composed entirely of spherical grains would have so little inherent stability that a pavement made with it would rapidly form into waves under the action of traffic.

The Mesh Composition of Paving Sands is Determined by passing them successively thru sieves having various square apertures.

The following method for making a mechanical analysis of sand or other fine highway material, except for fine aggregates used in cement-concrete, was adopted in 1916 by the Am. Soc. Test. Mat.

Meshes per Lin In (2.54 Cm)	Diameter of Wire	
	In	Mm
10	0.02700	0.68580
20	0.01650	0.41910
30	0.01375	0.34925
40	0.01025	0.26035
50	0.00900	0.22865
80	0.00575	0.14600
100	0.00450	0.11430
200	0.00235	0.05969

"The method shall consist of (1) drying at not over 110° C (230° F) to a constant weight a sample weighing 50 g; (2) passing the sample thru each of the following mesh sieves (Am. Soc. Test. Mat. standard sieves) (Note: The order in which the sieves are to be used in the process of sifting is immaterial and shall be left optional; but in reporting results the order in which the sieves have been used shall be stated); (3) determining the percentage by weight retained on each sieve, the sifting being continued on each sieve until less than 1% of the weight retained on each sieve shall pass thru the sieve during the last minute of sifting; and (4) recording the mechanical analysis in the following manner:

Passing 200-mesh sieve..................................	......%
Passing 100-mesh sieve and retained on a 200-mesh sieve......	......%
Passing 80-mesh sieve and retained on a 100-mesh sieve......	......%
Passing 50-mesh sieve and retained on an 80-mesh sieve.....	......%
....	......%
	100.00%

Sometimes, in sifting a sand it is first placed on the 200-mesh sieve and the amount passing thru that sieve is determined. The residue left on that sieve is then placed on the 100-mesh sieve and the amount passing thru it is next determined and so on thru the entire range of sieves. In this way the individual percentages will add up to 100. It is customary to speak of the grains passing the 200-mesh sieve as 200-mesh material or grains; that passing the 100-mesh sieve as 100-mesh material or grains, and this practice is followed thruout the entire range of sieves. The proper mesh composition of a sand varies with the traffic to which the pavement is to be subjected. In light traffic pavements, a coarser sand can be used than in heavy traffic pavements. This will be discussed at length under the theory of sheet-asphalt pavements.

Standards for the Mesh Composition of a Paving Sand are given below:

	Light Traffic		Heavy Traffic	
Passing 200-mesh sieve......	0 to 5%		0 to 5%	
Passing 100-mesh sieve......	10 to 15%	18 to 25%	10 to 25%	25 to 40%
Passing 80-mesh sieve......	6 to 15%		10 to 20%	
Passing 50-mesh sieve......	10 to 40%		5 to 40%	
Passing 40-mesh sieve......	10 to 30%		5 to 30%	
Passing 30-mesh sieve......	10 to 20%		10 to 15%	
Passing 20-mesh sieve......	10 to 15%		5 to 10%	
Passing 10-mesh sieve......	5 to 12%		2 to 8%	
Passing 8-mesh sieve......	0 to 5%		None	

It is but seldom that a single sand can be found which will fulfil these requirements. Mixing must therefore be resorted to and ordinarily a mixture of two sands will be all that is required. In some cases three and even four sands have been mixed before the necessary mesh composition was obtained. When more than one sand is being used it sometimes happens that the only available supply of a certain grade is composed of grains that are not wholly satisfactory as to composition or sharpness. Unless such a sand is wholly unsuitable its admixture with other sands of more satisfactory character will often remove what would be a valid objection to its use if it were employed alone.

Typical Examples of Admixtures of Two Sands are given below:

	1	2	3	4	5	6
Passing 200-mesh sieve	1%	0%	1%	6%	1%	3%
Passing 100-mesh sieve	23%	0%	15%	36%	1%	15%
Passing 80-mesh sieve	21%	0%	14%	37%	2%	16%
Passing 50-mesh sieve	48%	5%	34%	18%	38%	30%
Passing 40-mesh sieve	3%	7%	4%	2%	15%	10%
Passing 30-mesh sieve	4%	22%	10%	1%	18%	11%
Passing 20-mesh sieve	....	34%	11%	....	15%	9%
Passing 10-mesh sieve	....	23%	8%	....	10%	6%
Retained on 10-mesh sieve	....	9%	3%	....	....	....
	100%	100%	100%	100%	100%	100%

(1) Sand A. (2) Sand B. (3) Mixture of two parts of sand A with one part of sand B, satisfactory as to mesh composition. (4) Sand C. (5) Sand D. (6) Mixture of two parts of sand C with three parts of sand D, satisfactory as to mesh composition.

A Typical Example of the Admixture of Three Sands follows:

	7	8	9	10
Passing 200-mesh sieve	1%	13%	....	3%
Passing 100-mesh sieve	13%	45%	1%	16%
Passing 80-mesh sieve	11%	38%	15%	17%
Passing 50-mesh sieve	38%	2%	24%	28%
Passing 40-mesh sieve	13%	1%	15%	11%
Passing 30-mesh sieve	13%	1%	11%	10%
Passing 20-mesh sieve	11%	....	10%	9%
Passing 10-mesh sieve	....	....	24%	6%
	100%	100%	100%	100%

(7) Sand E. (8) Sand F. (9) Sand G. (10) Mixture of 9 parts sand E, 8 parts sand F, 4 parts sand G, satisfactory as to mesh composition.

Surface Character of Grains. This consideration is of the highest importance as it vitally affects the cementing qualities of the asphalt cement, and if this fails the entire pavement fails. The best sands in this respect are those which have rough, pitted surfaces similar to the Cowbay sands. Those which have been polished and worn smooth on the surface are not so desirable, as they will not take as thick a coating of asphalt cement. This is also influenced by the composition of the grains. Limestone grains are soft and porous and generally undesirable in paving work but a coating of asphalt cement adheres very strongly to them. Flint grains are extremely undesirable, as they take a very thin coating of asphalt cement and it does not adhere strongly to them. Some of these peculiarities in the attraction of certain types of grains for asphalt cement and *vice versa* are not easy to explain, as surfaces apparently identical act very differently in this respect. To be on the safe side, choose clean quartz grains with comparatively rough and pitted surfaces and avoid those having coated or polished surfaces and composed of flint. Where undesirable sands have to be used they should be mixed at as high a temperature as possible without injuring the asphalt cement and the time of mixing should be increased, thus insuring as far as possible satisfactory coating of the grains and adhesion of the asphalt cement to them.

Sources of Supply. Sand is finely divided rock detritus and has usually been deposited in the place where it is found by water action. Where the current has been swift or the water violently agitated, coarse sand is usually deposited, the finer grains being deposited from comparatively still water. Wind is also an important agency in the movement of sand, as witness shifting sand dunes in many localities. Air currents at high velocity will transport very coarse sand and even gravel, while at lower velocity only fine sand will be displaced. These facts often indicate where fine or coarse sands may be searched for with hope of success. In protected areas and where eddies are formed along river banks, deposits of fine sand will usually be found. Where the flow of the current is unrestricted the bed of the stream will usually produce gravel or coarse sand. Variations in current velocity due to natural causes will frequently produce very great changes within 24 hr in the mesh composition of sand dredged from a river or bay. According to the localities in which they are found, sands may be classified as follows: Beach sands, from sea and lake shores; river sands; and bank or pit sands.

Beach Sands from the Sea-shore are usually unsuitable for paving work. The grains are often polished and rounded to an undesirable extent, altho this is not always the case. They are usually composed largely of 80 and 50-mesh particles and if used would therefore require mixing with both fine and coarse sands to produce a satisfactory mesh composition.

Beach Sands from Lake Shores are frequently used in paving work. The grains of which they are composed are usually more rounded than is the case with bank sands, but in many instances this action has not taken place to an undesirable extent. The mesh composition of sands of this type does not ordinarily show such an excessive accumulation of 80- and 50-mesh grains as do sea beach sands. They are of course deposited thru water action, but this is ordinarily less violent and continuous than on the sea-shore, as there is no tidal action. Even when more rounded than wholly desirable, the admixture with them of sharp pit sands is frequently sufficient to remove this objection. Suitable paving sands are obtained in large quantities from Lake Michigan, Lake Erie, Lake Ontario and Lake Pontchartrain, typical siftings of which are given below:

	Lake Michigan	Lake Michigan	Lake Erie	Lake Ontario	Lake Pontchartrain
Passing 200-mesh sieve	1%	10%	1%	2%	0%
Passing 100-mesh sieve	3%	55%	9%	4%	0%
Passing 80-mesh sieve	5%	23%	20%	41%	1%
Passing 50-mesh sieve	31%	6%	39%	39%	25%
Passing 40-mesh sieve	20%	4%	20%	7%	50%
Passing 30-mesh sieve	15%	2%	6%	4%	19%
Passing 20-mesh sieve	13%	0%	3%	2%	4%
Passing 10-mesh sieve	12%	0%	1%	1%	1%
Retained on 10-mesh sieve	0%	0%	1%	0%	0%
	100%	100%	100%	100%	100%

River Sands are found either in beaches or in the beds of streams. In the latter case they are usually obtained by dredging, altho centrifugal pumps are also employed to a large extent for this purpose. They form a very important source of supply for paving work and are very varied

in character. River sands generally possess strongly distinguishing characteristics peculiar to the particular river from which they are obtained. This is due largely to the different rock formations from which they were derived and the prevailing conditions of flow, shape and kind of river bottom, etc. Attention must be called to the peculiarities of many of the river sands obtained in the United States in the Mississippi Valley. The bitumen of an asphalt cement does not appear to adhere to them as strongly as it does to sands from eastern or western rivers and mixtures made from them will carry less bitumen and usually mark up to an undesirable extent in hot summer weather, even tho they are entirely satisfactory from the standpoint of mesh composition.

Bank or Pit Sands are differentiated from the other types previously described by not having been deposited by recent or present action. Their original derivation includes every known source of origin and method of deposition; by the agency of river, sea, glacial or wind action. Bank sands cover a wider range of mesh composition than do river or beach sands and are therefore of the greatest value in the paving industry. They vary from what is really a fine gravel to the wind-blown sands of the far west, many of which latter are almost entirely composed of fine quartz particles which will pass a 200-mesh sieve. Where a fine tempering sand is required carrying high percentages of 100 and 80-mesh grains it is usually sought for and found in bank or pit deposits. When digging sands from a bank or pit, it is essential to see that the deposit is properly stripped and the top layer of loam removed from it; otherwise, as the face of the bank is cut into, the loam will fall down and become mixed with the sand. In some instances these deposits are stratified in comparatively thin layers so that by careful selection almost any desired mesh composition can be obtained from a single pit. Careful working of such a deposit is necessary to insure getting the proper proportion from the various strata, otherwise hopeless irregularity in output will result. Glacial sands are found in those parts of the country which during the Glacial Period were covered with an ice sheet. Bitumen appears to adhere with great tenacity to sands of this character, notably those obtained from Cowbay and other localities on the north shore of Long Island, N. Y., and such sands have been used with great success in paving work in New York City. The presence of undesirable quantities of clay or loam render many bank sands unsuitable for paving work, as this bakes on the surface of the grains sufficiently to adhere to them during the mixing process, thereby preventing the bitumen coating from coming in close contact with the true surface of the larger grains altho they may appear to be well coated. Under stress of service this baked coating is liable to come off and carry the bitumen with it. In other cases the clay or loam bakes into small balls of sufficient tenacity to pass thru the mixer without breaking up. These are coated on the outside with bitumen, but when laid in the pavement break open under traffic, revealing a mass of loose, uncemented material which washes out on the first application of water. This leaves a pit in the surface in which water accumulates and carries on its disintegrating action. Where only clayey sands are available, they may be rendered suitable for use by washing them. Certain sands have their grains more or less coated with a ferruginous cement, notably the red sands of New Jersey. This is also the case with many of the sands associated with the London gravels. An asphalt coating applied to these English sands has frequently completely washed off in less than a month and this has justly caused this

type of sand to be regarded with suspicion altho cases have occurred where entirely successful pavements have been laid with them. Sands in which the grains are largely composed of flint should be viewed with extreme suspicion, as it is difficult to get the bitumen to adhere properly to them. In a limited number of instances artificial sand produced by crushing stone has been successfully used by itself or mixed with natural sand in paving work.

Voids in Sand. Before the generally accepted grading for paving sands was determined, the question of voids was possibly regarded as of greater importance and interest than at the present time. It was at first considered that the total percentage of voids in a sand should be as low as possible and that all the voids should be completely filled with asphalt cement. Of recent years, however, the tendency has been to keep the voids as small in size as possible and use sufficient asphalt cement to thoroly coat all the particles regardless of whether or not this completely filled the voids. A solid block of stone would possess no voids at all, but it would not be a sheet-asphalt pavement; also, of two sands having approximately the same mesh composition and different percentages of voids, the one to be preferred would usually have the larger total percentage of voids and yet have them smaller in size than the other. So many considerations enter into the selection of a sand for paving use that there is a danger of too great attention being given to the subject of voids if one becomes an enthusiast on that subject. From a theoretical standpoint a sand composed of spheres of the same size should have approximately 26% of voids, but in practice it is impossible to obtain this figure owing to the difficulty of compacting the spheres to the maximum point and the nearest approach to it has produced a mixture showing 31% of voids. Where the grains are of uniform size the percentage of voids will vary with the shape of the grains but not with the size of them. This is clearly shown by the following table by Richardson (7).

Voids in Different Sizes of Crushed Quartz

	Voids
Passing 6-mesh sieve and retained on 10-mesh sieve	43.3%
Passing 20-mesh sieve and retained on 30-mesh sieve	43.4%
Passing 90-mesh sieve and retained on 100-mesh sieve	44.2%

Generally, rounded grains will pack more closely than sharp grains but, as already noted, rounded grains are not desirable. Where the grains consist of particles of varying size, the voids are lower than where they

	Percent Passing Different Sieves								Weight per Cubic Foot, Hot		Voids, Hot	
	200	100	80	50	40	30	20	10	Loose	Tamped	Loose	Tamped
Buffalo	17	24	15	24	10	4	4	2	98.5 lb	108.0 lb	40.3%	34.6%
Omaha, Neb.	5	13	34	31	8	3	4	2	.....	109.7 lb	35.8%	33.5%
Chicago	2	74	23	1	..	..	.	.	93.5 lb	100.3 lb	46.3%	39.2%
Detroit	2	10	23	59	4	2	.	.	97.2 lb	106.6 lb	41.1%	35.4%
Kansas City, Kan	10	15	23	44	6	1	1	.	97.4 lb	106.8 lb	41.0%	35.8%
Long Island Bank	10	12	8	27	15	12	7	9	100.3 lb	110.8 lb	39.2%	33.0%

are all of one size, and, as is to be expected, the finer sands usually show a higher percentage of voids than the well graded coarser ones carrying a reasonable percentage of fine material. This is shown by the preceding table by Richardson (7).

The addition of limestone dust or filler up to a certain point will still further reduce the voids in a sand but beyond that point they will gradually increase. The critical point appears to be approximately that where the amount of added dust exceeds the voids originally present in the sand. The addition of approximately 36% of filler to a sand originally containing 36% of voids will reduce them to approximately 20%, but it is not practicable or advisable to use this amount of filler for reasons which will be explained later. In calculations involved in the determination of voids the specific gravity of the particles in a quartz sand is usually taken as being 2.65.

Prospecting for Sand. Sand dealers who have not been accustomed to furnishing paving sand should be approached with the explanation that concrete or mortar sand is not being sought, as this type of sand is too coarse for paving work. It should be impressed upon them that something much finer or softer is desired. In many cases they consider that an asphalt sand is a loamy sand, tho this is really not the case.

5. Fillers

Essential Characteristics. This is used to fill in the interstices between the grains of sand in the wearing course and render it more compact and dense. Fineness is therefore an essential requirement. As very little of the sand used passes a 200-mesh sieve and as a considerable quantity of it does pass a 100-mesh sieve, it is apparent that the bulk of the filler should pass a 200-mesh sieve. Most specifications require that at least 66% of the filler shall pass a 200-mesh sieve. The finer the portion which passes the 200-mesh sieve the better the filler and two fillers, both showing the same amount of 200-mesh material, may vary very greatly in this respect. Generally speaking, a filler should be free from organic matter, should be composed of particles to which bitumen will adhere readily and should be capable of packing solidly together when dry. This last property adds greatly to the stability of the mixture to which the filler is added.

Materials Used as Fillers. A great variety of materials have been used as fillers, including rock dust of almost every sort, Portland cement, natural cement, ground silica, slacked lime, clay, marl, fine sand dust from dust collectors and ground waste lime from beet sugar factories. Of the different varieties of rock dust, ground limestone is undoubtedly the best and has been used more extensively than any other filler. For ordinary traffic conditions there is probably nothing better. It packs well when dry and asphalt cement adheres to it tenaciously and is to a certain extent absorbed by it. For streets carrying very heavy traffic, Portland cement or a mixture of Portland cement and limestone dust, is probably superior to limestone dust alone, as they undoubtedly add to the stability of the mixture and seem to increase its wear resisting qualities. The reason for this is not well understood, but a mixture made with a Portland cement filler will rake stiffer and stand up with a more vertical face when dumped from the wagon than will an otherwise exactly similar mixture made with a limestone dust filler. Natural hydraulic cement has been used with some success, but a number of unfavorable results have been attributed, perhaps unjustly, to its use and at the present time it is seldom employed. Ground

silica or quartz has been largely used in past years in pavements in New York City but it has fallen into disuse. Bitumen does not adhere to it as well as it does to limestone dust or Portland cement and mixtures made with it do not resist water action as well as do those made with the other two fillers mentioned. Slaked lime has been used in coal tar pavements but to a very small extent in sheet-asphalt work and can not be classed as a desirable filler. Clay would probably make an excellent filler were it not for the extreme difficulty of keeping it from balling after drying and pulverizing it. Entire roads have been constructed of bituminous sand-clay mixtures which have given excellent satisfaction. Ground marl has also been used in some instances but it is very light and its use renders work on the mixing platform very trying, due to the dust produced. Much of the finer material blows away during the mixing process. Sand dust is undesirable, as it does not pack dry and its use makes the mixture very mushy and lacking in stability. Ground waste lime from beet sugar factories contains an undesirable proportion of organic matter. The weight of experience is decidedly in favor of the use of limestone dust for ordinary traffic conditions and Portland cement where the traffic is exceptionally heavy. In wet climates it is especially unwise to experiment with fillers that have not proven themselves satisfactory from long experience.

6. Binder Stone

As the binder course does not take any of the actual wear of traffic but serves as an intermediate course between the foundation and the wearing course, the selection of the materials used in it does not require the same care as must be applied to the selection of a sand. Almost any variety of good hard stone may be used. The maximum size of the stone should not exceed three-quarters of the thickness of the binder course to be laid with it. For instance, with a 1½-in binder course the stone should all pass a 1⅛-in screen; for a 1-in binder course it should all pass a ¾-in screen. The stone should not be weathered or soft and should preferably be free from all particles which will pass an 8-mesh sieve. This insures a stone free from dust, which is desirable because stone which contains a large amount of screenings segregates very badly in a pile and because in stone containing dust, more especially if it has been weathered, the dust appears to adhere to the larger particles to such an extent as to prevent the bitumen from properly adhering to them. The stone should be graded from coarse to fine with a preponderance of the larger particles. The voids between these should be filled with the next size particles, and so on, thus producing a compact rigid mass in which the voids are reduced to the smallest size compatible with the materials used. Extreme smallness of voids, such as is striven for in the wearing course is not essential or desirable in a binder course. Gravel has been used as a substitute for broken stone, but it is not to be recommended, as a binder course made with it lacks rigidity and stability and, generally speaking, bitumen does not adhere as well to gravel as it does to broken stone

7. Refined Asphalts

Refined asphalt usually forms the basis of the asphalt cement which binds together the particles of the mineral aggregate of a sheet-asphalt pavement. In the earlier days of the industry the refined asphalt was always of such a hard consistency that it was necessary to soften it by the addition of a flux. At the present time a considerable proportion of

the asphalt employed in paving work is refined to the proper consistency for use and requires no fluxing. The refined asphalt must possess such properties that when ready to be used in the pavement, either with or without the addition of a flux, it will firmly bind together the mineral particles and resist the disintegrating action of traffic and the elements. These necessary properties will be discussed at length under ASPHALT CEMENT and the individual characteristics of the different asphalts will be found in Sect. 12, BITUMINOUS MATERIALS. The primary source of asphalt of all kinds is undoubtedly petroleum. Some petroleums consist chiefly of what are termed asphaltic hydrocarbons and others contain these constituents in very small proportion. Only the former class are suitable for the production of asphalt and asphalts found in a hard state in nature are undoubtedly derived from them. The asphaltic hydrocarbons are of complex structure and consist largely of saturated and unsaturated cyclic and polycyclic compounds and their non-metallic derivatives. In many localities, thru natural causes, asphaltic petroleum has lost its more volatile constituents by condensation or evaporation, or both, and has left behind a more or less solid residue of asphalt. These residues have in some cases filled natural depressions, from which has arisen the term ASPHALT LAKES. The crude material, either solid or liquid, requires refining before it can be used. The water and light oils are driven off by heat and the residue is employed for paving purposes. In the case of some of the hard native asphalts as much as 30% of water must be removed, while with some of the asphaltic petroleums as high as 60% of light oils must be distilled before the residue is of the proper consistency. During the earlier stages of the industry great stress was laid on the merits of asphalts coming from certain deposits or localities, but, as the knowledge of the art of paving increased, the really essential qualities necessary for a paving asphalt were pretty definitely ascertained and methods for determining them became fairly well standardized. At the present time among those who are posted upon the subject, the source of an asphalt is not necessarily regarded as any index of its quality. It must in every case fully meet standard requirements. In this connection it must be borne in mind that different asphalts have their individual characteristics, which in many instances sharply differentiate them from all other asphalts and their efficiency for paving purposes is to a certain extent represented by the mean of their various physical and chemical properties. One asphalt may possess a certain quality to a much higher degree than another, but this does not necessarily mean that it is better for paving purposes, as the other asphalt may and probably will have its particular points of superiority also. No one asphalt can be said to be preeminently superior to all others in every respect. It is unwise to attempt to set a definite absolute minimum permissible standard for any one physical or chemical property because a certain asphalt might have its low standard in one particular respect offset by certain other high qualities. To apply this low standard without restriction to other asphalts which do not possess the offsetting qualities would be dangerous in the extreme. Because of this and because physical and chemical tests are not always absolutely conclusive in the present state of our knowledge, service tests are of great value in determining the fitness of an asphalt for paving purposes. A knowledge of the kind of crude material from which an asphalt is derived is extremely valuable because, when the asphalt is manufactured strictly in accordance with modern methods of refining from a particular crude material, it will possess

certain characteristics and a product from this crude which varies markedly from this standard should not be unreservedly accepted as fit for use until its worth has been proved. The argument that even in spite of such a departure from standard methods it is still superior in all respects to the minimum acceptable for all other kinds of asphalt should not be given weight for the reasons above stated. It has not been possible to define the effect of variations in any one physical quality in terms of increased requirements in other qualities. In all cases, therefore, the refining must be carried on with care and by the most approved methods in order to insure the production of an asphalt of good quality. The finished product is of varying degrees of purity, depending on the kind and source of the crude material and it is generally sold in wooden or iron barrels or in tank cars.

8. Fluxes

The fluxes now in use are the liquid residues left after distilling off the lighter products from petroleum. At first, residuums from paraffin base petroleums were used almost exclusively altho a few natural malthas were employed to a limited extent. Some of these fluxes contained as high as 30% of scale paraffin, tho the average was 8 to 12%, and asphalt cements made with them consisted of 25% of flux and only contained 65% of bitumen. The bitumen in these asphalt cements, therefore, contained from 3 to 9% of scale paraffin. Judging from the excellent service record of many of these pavements, the presence of this amount of scale paraffin in the bitumen could not have been detrimental, altho much has been said as to the harmfulness of this ingredient. Of late years the use of asphalts containing up to 5% of scale paraffin has become wide spread and their service records are excellent, so that the question of paraffin contents is no longer generally considered as of prime importance. Most natural malthas rapidly harden on heating and produce hard, pitch-like residues. Their use has therefore been abandoned. Residuums prepared from asphaltic and semiasphaltic petroleums are generally considered superior as fluxes to paraffin residuums, owing to their asphaltic nature. The bulk of the fluxes now employed are of this character. A flux to be suitable for use in the paving industry must be permanent in character and stable under heat. It must be a good solvent for the bitumen of the asphalt which is to be softened with it and must combine with it in such a manner as to produce an asphalt cement possessing the necessary properties. Unless a flux is free from light oils, these oils will evaporate in the pavement and soon leave the bitumen so hard that the pavement will crack. Unless they will stand exposure to the elements without being rapidly affected by them, a similar result will take place. They are mixed with the asphalt at temperatures from 149° C (300° F) to 177° C (350° F) and the asphalt cement so produced is sometimes kept at or near this temperature for several days. If they decompose or volatilize to any considerable extent under these conditions, asphalt cements made with them will harden rapidly in the melting kettles and require the addition of more flux and such a residuum would probably also harden rapidly in the pavement with the effect above described. Unless they are good solvents for bitumen they will not properly soften a hard asphalt and produce a homogeneous cement in which the hard bitumens are completely dissolved in the softer ones and this will result in a low cementing value of the asphalt cement. If the flux is a poor solvent for the bitumen, much

more care and time must be taken in the preparation of the asphalt cement to insure a complete solution. With limited kettle capacity this is a very important consideration. Certain fluxes are suited for use with certain asphalts and not with others. In some cases this is due to their solvent action, but this is not the only consideration. Certain asphalts are lacking to a greater or less extent in certain constituents and this lack can often be supplied by the use of a suitable flux. Other fluxes may be equally good solvents but may not contain sufficient of the lacking constituents and an asphalt cement made with them might be totally unsuitable, or at best of poor quality. An exhaustive examination of both asphalt and flux might be sufficient in some cases to determine this without a physical test, but chemical analyses do not always reveal physical defects and it is customary therefore to actually flux some of the asphalt to be used with the flux under examination and test the physical properties of the resulting asphalt cement. Because a certain flux gives good results with a certain asphalt is no criterion that it will be equally suitable for another kind of asphalt. Some fluxes of course are more universally suitable than others. In most cases an undue amount of cracking in the preparation of a residuum is undesirable as it is liable to produce unstable compounds in the residuum. Sometimes, however, this is not the case, as a certain amount of cracking may result in the formation of more stable compounds than those originally present, provided the light oils produced are removed by distillation. Desirable fluxes should all stand heating to 163° C (325° F), for 5 hr without losing more than 5% or becoming hard and should flash above 177° C (350° F) to insure safety in the plant. Flux is usually purchased in barrels or tank cars.

9. Asphalt Cements

Essential Characteristics. As previously indicated, this term is applied to the bituminous cementing material which is used to bind together the mineral particles entering into the composition of a sheet-asphalt pavement and is prepared either by refining liquid bitumen to the proper consistency or by mixing a hard asphalt with a suitable flux. However prepared, it is essential that it should possess certain properties in order to fit it for use in the asphalt paving industry. These may be discussed under the following heads: (1) Permanence when exposed to climatic and traffic conditions; (2) permanence when exposed to working temperatures in the manufacture of the pavement; (3) lack of undue susceptibility to changes in temperature; (4) purity; (5) cementing value; (6) ductility.

Permanence under Climatic, Traffic and Manufacturing Conditions. The coating of asphalt cement which is applied to each sand grain is necessarily very thin and great permanence is therefore required to enable it to resist the deteriorating influences of traffic and weather. Only those grains which are on the surface of the pavement are directly exposed to climatic influences and as they wear away the grains below form a new surface. If this wear is too rapid the pavement will not last as long as it should. Once the bitumen has lost its cementing power the grains become loose and are washed or swept or blown away, or ground out under traffic. Asphalt pavements are expected under normal conditions to give an average of 10 years of service and during summer time in a temperate climate often attain a temperature of 60° C (140° F) or over. In winter, a pavement often reaches a temperature below −18° C (0° F) and in many cases pavements are continually wet with no opportunity of drying out for

weeks at a time. During all these severe conditions they must successfully carry the traffic passing over them, so that the conditions affecting permanency are very severe indeed. The asphalt cement must resist the disintegrating and deteriorating effect of high and low temperatures and extreme wet, for on its ability to resist these influences depends the whole integrity of the pavement.

Non-Susceptibility to Changes in Temperature. When the same mineral aggregate is used pavements made with asphalt cements possessing different physical properties will vary very considerably. Some asphalt cements are much more affected by changes in temperature than are others; that is, become softer in summer and harder and more brittle in winter. Within limits, this tendency, more especially the softening in summer, may be counteracted by the more careful selection and grading of the mineral aggregate. The use of a sharper and better graded sand and an increase in the quantity of dust or filler will increase the stability of the mineral aggregate and render the pavement less soft in summer. Under the conditions ordinarily prevailing, asphalt cements which vary considerably in susceptibility to changes in temperature may be successfully employed. In certain localities, however, it is impossible to secure sands of the best type, as previously noted under sands, and under these conditions it may be necessary to limit the susceptibility to changes in temperature of the asphalt cement used.

Purity is essential up to the point where it is possible to use the asphalt cement as a cementing material. A mixture containing only 25% of bitumen could hardly be regarded as an asphalt cement. Excessive quantities of mineral matter would make it very difficult to melt such an asphalt cement and keep it in such a state of agitation that it would have a uniform bitumen content. Undesirable impurities which would tend to rot or disintegrate the pavement should also be excluded.

Cementing Value. The chief, if not the only, function of the asphalt cement in a pavement is to bind the particles of the mineral aggregate together so that it will sustain the traffic. It is essential, therefore, that it should possess cementing value to a very high degree. From a theoretical standpoint the degree required would depend upon the service conditions. Where the sand is properly graded and the grains are thus brought together in close contact, it is perhaps fair to assume that less cementing value is required than when the grading is poor. Similarly an asphalt cement which is low in cementing value might be successfully employed on light traffic streets altho it would fail under heavy traffic. Certain sands are much more difficult to coat than are others and in such cases a very high degree of cementing value in the asphalt cement is absolutely essential. From the practical standpoint, however, the severity of the conditions met with in service makes it extremely dangerous to set up anything but a very high standard for the cementing value of all asphalt cements used in paving work. A light traffic street of to-day may become a heavy traffic street of to-morrow and the science and art of paving has not reached that stage where it is possible to prescribe definite cementing values for certain conditions.

Ductility. Pavements are frequently subjected to very rapid and great changes in temperature, which inevitably produce expansion and contraction. Unless the asphalt cement possesses sufficient ductility, this will result in the cracking of the pavement and for this reason ductility is considered as one of the necessary qualities of an asphalt cement. When

the pavement is subjected to a considerable amount of traffic, the stresses set up by contraction and expansion are equalized to a considerable extent and for this reason pavements on light traffic streets are more liable to crack than are pavements on streets carrying heavy traffic.

10. Theory of Sheet-Asphalt Pavements

Broadly speaking, the governing principles are: (1) The selection of a mineral aggregate of sufficient hardness and denseness to resist the abrasive action of traffic; (2) binding the various particles of the mineral aggregate together in such a way that the pavement will maintain a smooth surface and resist the disintegrating action of traffic and the elements.

General Functions of Sand, Filler and Asphalt Cement. Relative cheapness of the various ingredients is of course essential. It is probably correct to assume that sand is the last and most permanent stage of the mineral ingredients of the earth's crust and sooner or later all rocks when exposed to weather become reduced to the state of sand. If the sand particles were bound together with a rigid cementing material it would make a hard unyielding pavement and a more or less noisy one and expansion and contraction would play a large part in its disintegration. By using a non-rigid bituminous cement many of these disadvantages are overcome. As the bituminous cement, however, becomes soft in summer the requisite stability of the pavement in hot weather must be secured by proper grading of the sand and mixing it with a sufficient quantity of finely ground mineral filler so that the voids between the mineral particles shall be reduced to the smallest practicable size. The consistency of the bituminous cementing material must be such that it will not be too brittle in winter or too soft in summer and it must adhere tenaciously to the grains, bind them together firmly and resist traffic and weathering. These broad general principles were far from being well understood at the commencement of the industry. At that time sand was sand and the function of the filler was not clearly recognized and what constituted a good asphalt or a bad asphalt was largely a matter of advertising and clever promotion work. The two factors influencing the design of a sheet-asphalt pavement to meet specific requirements are traffic and climatic conditions and these affect both the mineral and bituminous ingredients. Where the traffic is dense and consists largely of slow moving, heavily loaded, iron-tired vehicles, it is evident that the crushing strain on the individual sand grains will be very great. Where a sand grain is crushed it leaves a depression in the pavement in which water can collect and where a large number of these grains are crushed this has a very serious effect upon the life of the pavement, more especially in wet climates. For very heavy traffic of this kind it is, therefore, essential that the proportion of 10 and 20-mesh grains should be very small and in pavements laid in Glasgow, Scotland, where the climate is very wet and the traffic was extremely heavy practically no grains coarser than 40-mesh were employed. This produced a pavement which in very hot weather would have been somewhat lacking in stability, but as the summer temperatures in Glasgow are comparatively low, this was not a serious defect. The stability of the mineral aggregate is greatly increased by the presence of 10 and 20-mesh grains and where they are absent this must be compensated for by the use of a filler which gives the maximum stability and if necessary by the use of a slightly harder asphalt cement.

Sheet-Asphalt in Dry and Wet Climates. In very wet climates, espe-

cially when the traffic is heavy, the coating of bitumen on the sand grains must be thicker than is required under drier conditions and the temperature at which the ingredients are mixed, as well as the duration of the mixing process should be increased in order to insure the maximum adherence of the bituminous coating to the sand grains. The difference between wet and dry conditions on a sheet-asphalt pavement in which the grains were thinly coated with bitumen is clearly shown by a test at the National Physical Laboratory, at Teddington, England, in the winter of 1914–1915. This test was conducted by The Road Board of Great Britain on its specially designed road machine. In this machine iron-tired wheels, each provided with its own motive power and which can be loaded to any desired extent, pass over the surface of the test pavement which is laid on the concrete foundation of a circular track. The same mixture had been laid on a considerable area of roads in the immediate vicinity of Teddington, and during the dry weather immediately following their construction, gave excellent satisfaction. This was followed by a period of unprecedently wet weather during which the roads broke up very badly and it was then decided to test the mixture in the road machine. The mixture which had failed was accordingly duplicated, using the same materials, machinery and men and laid on the track of the testing machine. Analyses of the old and new mixtures showed them to be substantially identical. The test pavement analyzed as given in column A.

	A	B
Bitumen	8.9%	11.6%
Passing 200-mesh sieve	7.0%	14.7%
Passing 100-mesh sieve	9.2%	8.4%
Passing 80-mesh sieve	15.6%	10.0%
Passing 50-mesh sieve	37.0%	28.3%
Passing 40-mesh sieve	12.0%	13.4%
Passing 30-mesh sieve	6.6%	7.8%
Passing 20-mesh sieve	2.5%	3.4%
Passing 10-mesh sieve	1.2%	2.4%
	100.0%	100.0%

Under a dry test this pavement lasted for weeks and showed no signs of undue wear. The test was then conducted under the same conditions except that the surface of the pavement was kept continually wet and it then broke up so badly that the machine had to be stopped within a few hours from the time that the wet test commenced. In order to prove that the materials used were not at fault, a mixture using the same machinery, men, sand and bitumen was made and tested in the road machine. Owing to the limitations imposed by the conditions of test, the grading could not be greatly improved but the quantity of filler and asphalt cement was increased. This mixture analyzed as given in column B, and stood, without breaking up, the test given in the table on following page. For purposes of comparison it should be stated that the best test which any mixture has ever given under similar conditions on this machine, which was purposely designed to test pavements to destruction in a comparatively limited time, was: Dry test, 11 hr, 27 min; wet test, 96 hr.

Dry Test

Duration	Total Load per Wheel	Speed of Wheels
75 min	3 cwt	1 mile per hr
120 min	6½ cwt	1 mile per hr
165 min	10 cwt	1 mile per hr
120 min	12½ cwt	1 mile per hr
100 min	15 cwt	1 mile per hr
107 min	20 cwt	1 mile per hr
11 hr 27 min	11.3 cwt average load	1 mile per hr

Wet Test

Duration	Total Load per Wheel	Speed of Wheels
50 hr	12½ cwt	6 miles per hr

Sand Grading and Bitumen Content. Under light traffic a sand containing a comparatively large proportion of coarse grains is desirable for several reasons. The finer the grains the greater the surface area to be covered with bitumen. This can be readily understood from a consideration of the following: A 1 ft cube has six sides each 1 sq ft in area. Cut it in two and there are eight sides of the same area and each time it is cut new surfaces are created. Of two pavements each having the same bitumen content, the one containing the larger proportion of coarse grains will therefore have the thicker coating of bitumen on the grains, owing to the smaller surface area which the given quantity of bitumen has to cover. The kneading action of traffic upon a pavement tends to equalize the stresses set up by contraction and expansion and to keep the life in the bitumen. Where the traffic is very light, all asphalt pavements have a tendency to crack for the above reasons and, other things being equal, those in which the grains are thinly coated with bitumen crack first. Increasing the amount of bitumen in a fine grained heavy traffic mixture would tend to remedy this, but too much bitumen would render it sloppy, and it would be much more expensive to lay than the coarser mixture carrying a lower percentage of bitumen and the coarser mixture would carry the light traffic just as well. The sand gradings which have been found to give the best results in practice for stability and wear are given elsewhere under sand, as well as the effect of rounded grains and different surfaced grains. With the standard grading the normal bitumen content of pavements in the United States varies from 10.5 to 12% and except under special conditions this gives satisfactory results. In England, where the climate is much wetter and the extremes of temperature not so great, the percentage of bitumen varies from 11 to 13. Where, on account of excessive moisture, the bitumen must be increased and the variations in temperature are great, Portland cement is perhaps the best filler to use, as it increases the stability of the mineral aggregate to a marked extent. It is also advisable to increase the amount of filler used up to a maximum of 20% of 200-mesh filler in the mixture.

Asphalt Cement. On a very heavy traffic street the stability of the mixture as well as the cementing strength of the bitumen is increased by

hardening the asphalt cement. The average penetration of all asphalt cements used in sheet-asphalt pavements laid at the present time in the United States lies somewhere between 50 and 60, but on very heavy traffic streets, even in fairly cold climates, as low as 20 has been successfully used. On a light traffic street a pavement laid with a 20 penetration asphalt cement would inevitably crack badly but under heavy traffic the contraction stresses are equalized almost as soon as they are set up and hence cracking does not take place. For normal traffic it is desirable to use as soft an asphalt cement as possible to offset the hardening effect of time on all bituminous cements. To do this successfully requires that especial attention be given to the stability of the mineral aggregate. This stability is governed by three main factors: (1) Grading of mineral aggregate; (2) shape of sand grains; (3) kind and amount of filler used.

Grading of Mineral Aggregate. In an ordinary sand mixture a certain proportion of 10, 20 and 30-mesh grains add greatly to stability and the 10-mesh particles add relatively more than do the 20 and 30-mesh particles. Provided the balance of the grading and the shape of the grains are satisfactory, a mixture containing 5, 8 and 10% of 10, 20 and 30-mesh grains respectively, will have the requisite stability. Increasing the percentage of these size grains up to a reasonable amount will, under the conditions stated, increase the stability, but when the traffic is heavy, this is objectionable for the reasons previously given. Where larger sized particles are used, as in binder, care must be taken not to use enough fine material, such as sand, to force the larger particles apart, as this will reduce the stability of the mixture. In binder the maximum stability is secured by permitting the large particles of stone to interlock as closely as possible and filling up the spaces between them with just enough sand to reduce the size of the voids. In this way the stones are held more firmly in place by increasing the contact area of the bitumen coated particles. Where stone alone is used, more especially if it is not well graded, but comparatively few parts of any one particle are in contact with other particles and the effective cementing action of the bituminous cement is therefore reduced to the minimum. Where the mixture contains 10 to 20% of particles passing a ½-in screen and retained on a ¼-in screen, the balance being made up of particles passing a 10-mesh sieve, a very slight excess of bitumen renders it very unstable. In such a mixture the larger grains are forced apart by an excess of fine material and they are sufficiently large to allow traffic passing over them to exert a leverage action upon them tending to displacement of the pavement. This is not the case with 10, 20 and 30-mesh grains. Beyond a certain size, therefore, the addition of coarse material does not tend to increase stability unless it is carried to the point where the coarser grains are permitted to interlock to the maximum extent possible.

Shape of Sand Grains and Kind, and Amount of Filler. Grains which are comparatively round, and therefore move upon each other readily, are much less stable than angular grains. The increased stability obtained by the addition of finely ground filler to a sand can readily be observed by mixing filler with sand in varying proportions and consolidating the dry mixture by successively placing small amounts of it in a cylindrical vessel from 1 to 2 in in diameter and 10 to 12 in high and consolidating it by tapping. Care should be taken to avoid segregation. After a sufficient amount of filler has been added, it will be possible to turn the cylinder upside down without any of the mixture running out. In other words

it will pack dry. Up to a certain point the ability to pack dry will increase with an increased proportion of filler. Beyond that point, which varies with different sands, it will apparently decrease until the point is reached where the mixture consists very largely of filler, when it will again increase. For this reason mixtures composed almost wholly of 100 and 200-mesh angular particles, such as are found in French, Italian and German rock asphalt pavements, are exceedingly stable. There is not much apparent difference between dry mixtures made up of the same sands using limestone and Portland cement fillers respectively of the same degree of fineness. When the bitumen is added to the mixture, however, the one in which Portland cement was used will be considerably stiffer to rake and will possess the greater stability. The cause for this is not clearly understood, but it evidently can not be due to any setting action of the Portland cement, as the grains are all covered with asphalt cement, thus excluding moisture from them and the effect is noticeable as soon as the hot mixture is made or dumped upon the street. The filler is almost always added cold to the hot sand just before it is mixed with the asphalt cement. If it were added to the cold sand and fed with it to the drying drum, much of the filler would be carried off as dust by the draught, besides which the limestone might be decomposed by the heat and segregation would inevitably take place in the hot sand bin. The different batches would consequently vary very greatly in mesh composition. The maximum amount of cold filler which can be added to a mixture obviously depends upon the ability of the hot sand to bring the mixture of sand and cold filler up to the proper temperature for mixing it with asphalt cement. Too much filler would chill the sand to an undesirable extent. It would also increase the amount of bitumen required by the mixture and beyond a certain point might render it sloppy. For these reasons the amount of filler added rarely exceeds, under normal conditions, 18% of the mixture. Some asphalts, such as Trinidad and Mariel (Cuban), contain a large proportion of finely divided mineral matter which acts as a filler in the mixture and this reduces the amount of filler necessary to add when such asphalt cements are used. Amorphous and colloidal fillers, such as clay, absorb the bitumen with which they are coated and their particles therefore retain the coating much more tenaciously than do crystalline and non-absorbent particles. This is undoubtedly one of the reasons why the use of clay as a filler is indicated from a theoretical standpoint. For the same reasons mixtures made with a limestone filler resist water action much more strongly than mixtures made with a ground silica filler. When determining the amount of filler to be added to a mixture consideration must be given to: (1) Traffic and climatic conditions; (2) kind and grading of sand; (3) mesh composition of filler; (4) mineral contents of asphalt cement. In very wet climates more filler should be used than is necessary under drier conditions in order to make a mixture in which the voids are of minimum size, thus preventing water from entering the pavement. Under these conditions the percentage of 200-mesh filler in a mixture may be carried as high as 20%. Under favorable climatic conditions, with light traffic and good sands, the 200-mesh material in the mixture may vary from 8 to 12%. Under heavy traffic the limits may be considered as lying between 10 and 15%. As previously noted, 200-mesh sand is undesirable in a pavement, as it tends to make a mushy mixture and should not be regarded as a filler. Where a sand of suitable mesh composition, as described under SAND, contains practically the same amount of 100 and 80-

mesh grains, more filler can be added to it in certain cases than if the proportion of 80-mesh grains was low. Mixtures deficient in 100 and 80-mesh grains, especially the latter, are liable to ball up and rake with extreme difficulty if the normal amount of filler be added to them. The true remedy of course is to secure sand with a proper amount of 80-mesh material in them. If this is impossible, it is better to use an asphalt cement which is extremely fluid at ordinary working temperatures, such as California asphalt, rather than to reduce the amount of filler used below the generally established limits. Generally speaking, sands of rather unsatisfactory mesh composition and having rounded grains require more filler than do sands of more suitable character. With sands of this character it is desirable to use an asphalt cement which does not readily become fluid on the application of heat.

Determination of Amount of Filler and Bitumen. It is of course always necessary to determine what percentage of filler will pass a 200-mesh sieve. If a mixture is desired containing 15% of 200-mesh material derived from the filler alone, and the filler contains 75% of 200-mesh material, it will be necessary to use 20% (15% ÷ 75%) of the filler in the mixture. The mineral contents of an asphalt cement will of course depend upon the composition of the refined asphalt used in it. Let it be assumed that the refined asphalt to be used contains 60% of bitumen and that the balance is finely divided mineral matter which can properly be regarded as a filler. Assume further that 20 lb of flux per 100 lb of refined asphalt is to be used in the preparation of the asphalt cement and that this asphalt cement will be kept continuously and thoroly agitated. Its mineral and bitumen contents would be determined by the following calculation: 100 lb refined asphalt containing 60% bitumen = 60 lb pure bitumen; 20 lb flux containing 100% bitumen = 20 lb pure bitumen. Hence, 120 lb asphalt cement will contain 80 lb pure bitumen, equivalent to 66.6% of bitumen. The balance, 33.3%, in this case is all mineral matter which was assumed to be a satisfactory filler. If the mixture is to contain 11% of bitumen, 16.5% (11% ÷ 66.6%) of this asphalt cement must be added to it. From the asphalt cement, therefore the mixture would derive 5.5% (16.5 − 11) of filler and if a total of 10% were desired, only sufficient filler must be added to insure the presence of 4.5% (10 − 5.5) more. If the filler contains 75% of 200-mesh material, this would require 6% (4.5% ÷ 75%) of filler to be added to the mixture. The proper amount of bitumen to add to a mixture is not always possible to determine in advance. With a normal sand and standard grading it usually varies from 10.5 to 11.5% in the United States. As previously explained, it is a function of the surface area of the grains to be covered taken in connection with the thickness of the coating desired to meet the conditions involved. Generally speaking, a mixture in which the grains are sufficiently covered will produce a stain on manila paper if the hot mixture is placed on it, the paper folded over and a smart blow given to it. The hotter the temperature of the mixture the deeper the stain. Bitumens which are very liquid at 149° C (300° F) will give deeper stains than those which are less liquid, so that a certain amount of skill and experience is necessary before the results of the pat test can be correctly interpreted. Once this is acquired, the pat test is a most valuable one for use with normal mixtures. Where the conditions call for an excessively rich mixture the test is of no use, as the paper is stained so heavily that no conclusions can be drawn from it. It frequently happens that two sands may have exactly the same mesh composition and yet one will require 2 or 3% more

bitumen than the other. Preliminary examination of the sand will not always reveal this, but the pat test will invariably demonstrate it conclusively. It is also generally, but not so positively, indicated by the appearance and working of the mixture. Certain sands with rounded grains will not take as much as 10.5% of bitumen without making a mixture which is undesirably sloppy. To the trained eye, the working of the mixture on the street will usually suggest what changes should be made in it, and this has been discussed at length under methods of laying. As all batches of surface mixture are based on a definite weight of sand, it is customary to give the plant foreman a formula based on 100 lb of sand. If the plant used measures the sand instead of weighing it, the volume of the sand box must be ascertained as well as the weight of a cubic foot of the dry hot sand which is to be employed. A simple calculation will then give the number of pounds of sand per batch. Assume that the sand and filler have been examined and that the asphalt cement has been determined as shown above, or by actual analysis, to contain 66.6% of bitumen. Also assume that it has been decided to add 15 lb of filler to every 100 lb of sand and that the finished mixture is to contain 11% of bitumen. The number of pounds of bitumen to add to the above mixture of sand and filler can readily be calculated as follows: a = lb of sand and filler = 115; b = percent bitumen in asphalt cement = 66.6%; c = percent bitumen desired in pavement = 11.0%. Then

$$\frac{a \times c}{b - c} = \frac{115 \times .11}{.666 - .11} = \frac{12.65}{.556} = 22.75 \text{ lb}$$

Hence the formula will be: Sand, 100 lb; dust, 15 lb; asphalt cement, 22.75 lb. If the contents of the sand box were found to weigh, for example, 850 lb, all the figures in the above formula would require to be multiplied by 8.5 (850 ÷ 100).

In connection with the foregoing discussion, the following table showing the composition of pavements laid in various cities of the United States and Great Britain may prove of interest.

The English mixtures are typical heavy traffic mixtures for wet climates. The Seattle mixture is for medium traffic and a wet climate. The poor Ottawa mixture cracked very badly while the one designated as good has given very satisfactory service. The poor Montreal mixture also cracked very badly. The balance of the mixtures are for medium to heavy traffic and normal rainfall with the exception of the old Washington, D. C., mixture, which, while very unorthodox, gave good results under very light traffic and the New Brunswick mixture, which may be regarded as a typical light traffic mixture.

11. Inspection and Sampling of Materials

Broadly speaking, a comprehensive system of inspection of bituminous materials and pavements or roadways made from them may be subdivided as follows: (1) Preliminary inspection of raw materials; (2) inspection of materials and processes during construction work; (3) inspection of finished work.

Preliminary Inspection of Raw Materials. These are, or should be, assembled by the contractor sufficiently in advance of starting the work to permit of their being tested. They usually consist of refined asphalt or asphalt cement; residuum flux; crushed stone or gravel; sand; and filler. All of these materials should be sampled from deliveries actually on hand on the work. Except where the manufacture of the material

is inspected at the refinery, this rule should never be departed from in the case of the bituminous materials themselves; that is, the refined asphalt or asphalt cement and the residuum flux. In the case of the materials which constitute the mineral aggregate of the pavement or roadway, contractors are often unable to judge themselves whether or not a particular material passes the requirements of the specifications and before placing their order for them they frequently submit samples obtained from different dealers for approval. In the case of crushed stone or gravel, these samples usually fairly represent the kind of material which will be delivered. This is also true in the case of filler. With sands, however, samples submitted by the dealers frequently vary very greatly from actual deliveries. It often happens that the selection of sand has not been given sufficient attention or has been deferred until the last moment, with the result that no really suitable samples are submitted. In such cases it is frequently to the interest of all parties concerned, altho perhaps not strictly the duty of the inspector, to personally visit and examine available sources of sand in the immediate neighborhood. In this way much better material may often be obtained than would otherwise be the case.

Sand and gravel banks are usually stratified and where the deposit has been made from comparatively still water the lower strata will usually contain coarser material than the upper strata. In every case the sand dealer should be impressed with the necessity of carefully stripping the top of the bank to remove deposits of clay, loam, etc, as this material is undesirable and will usually ball up in the heating drums. Where the strata vary considerably and can not be dug separately, it will be necessary to take an average sample of the run of the face of the bank in order to determine what will be the composition and character of the average output of the deposit. In certain cases it is necessary to select definite strata and have all the sand taken from them. In other cases the sand is dredged from river or creek beds and in order to obtain a satisfactory supply it is sometimes necessary to go on board a dredge with a set of screens and a sand scale and sample the sand obtained from various portions of the river-bed. When prospecting outlying country for available sand deposits, a small frying pan is a very convenient utensil to carry, together with the sand sieves and scales. By means of it, samples of sand taken from various pits can be dried over a small fire and sifted on the spot, which avoids the necessity of carefully marking them for identification and taking a lot of samples back to the laboratory or office. When securing samples of materials for examination, these should be carefully selected so that they really represent an average of the materials. The quantities necessary for examination are about as follows: Refined asphalt or asphalt cement, 1 lb; residuum flux, ½ to 1 quart; crushed stone or gravel, 1 to 3 lb; sand, 1 lb; filler, ½ lb. When these are sent to a central testing laboratory they should be plainly marked with the following information: Kind of material; date material was received at paving yard; date when sample was sent; quantity of material represented by sample; name of manufacturer or from whom purchased; name of paving contractor who is to use the material represented by the samples; name of city or town in which work is being done.

Method of Obtaining Samples. Refined Asphalt. This is usually shipped in barrels containing from 300 to 500 lb each. It will depend on circumstances and the quantity of material on hand how many barrels should be examined. Where the barrels are marked with the dates or batch

numbers and different batches are represented, it will usually be sufficient to take a single sample from each batch. Certain specifications give a permissible limit of variation in the penetration or consistency of different shipments of asphalt. In such cases it will be necessary to test for penetration a sample from each batch number, in which case all of the samples taken must be kept separate. Where no such provision is included in the specifications and the inspector is assured from his past experience that the particular manufacturer from whom the material was purchased is careful in his output, a fewer number of samples will be necessary than under other circumstances. In some cases an average sample made up of different samples taken from the requisite number of barrels will be all that is required. The packages or barrels used by different manufacturers are very often characteristic of the product, and this is also true of the odor and general appearance of the material. A qualified inspector will often be able to determine from observation whether or not the contractor's statement as to the source of the material which he intends to use is correct. In taking the samples, material should be selected which is free from dirt, etc, and which has not been exposed to the air. In other words, a piece of refined asphalt should not be taken from the top or immediately adjacent to the outside of the barrel.

Asphalt Cement. This is quite often shipped in tank cars and in such cases a single sample taken, preferably after the contents of the car have been melted, will be sufficient.

Crushed Stone or Gravel. Various samples from different portions of the pile should be taken and mixed together, and from the mixed portion sufficient should be selected for test. It is always advisable to dig into the surface of the pile a little way in order to get material which has not been exposed to the atmosphere and which possibly has lost thru the action of wind or rain, or both, a considerable portion of its fine material.

Sand. It is almost impossible to secure a fairly representative sample of dry sand, as the coarser grains have a different angle of flow from the finer grains and are found in different portions of the pile. The pile should always therefore be dug into some distance below the surface until damp sand is reached. After sampling the pile in this way in a number of places, the samples so obtained should be mixed together and sufficient taken for test from the mixed lot.

Filler. This is usually Portland cement or finely ground limestone dust, and comes in bags. No particular difficulty attends the sampling of this material, but a sufficient number of bags should be opened and samples obtained from them and mixed together in order that the sample sent for test shall correctly represent the average quality of the material.

The examination of the samples so obtained is usually conducted in accordance with detailed specifications. As these vary somewhat in their requirements, it is impossible to lay down a general rule which will cover the examination of raw materials for paving work. After the materials have been examined in the laboratory and found to be suitable for the work and in accordance with the specifications, the inspector can frequently be of great service in suggesting to the contractor the best formula to use. All paving specifications allow considerable leeway as to the composition of the mineral aggregate and the percentage of bitumen required in the mixture. Sometimes the decision lies entirely with the engineer on the work and where he is fully competent to decide these questions it should, of course, be left to him. As the contractor usually has to assume a guar-

antee on the completed work, he naturally feels that he should be consulted as to the formula used. Sometimes his desire to reduce the cost of his work will lead him to employ a formula which, while complying with the minimum requirements of the specifications, is really not suited to the work in hand. Whenever possible, cooperation between the inspector and the contractor will always secure the best results and a little tact used in this connection will usually be all that is required. It frequently happens that two or more kinds of sand or stone have to be mixed together in order to secure a suitable mineral aggregate. Many contractors are exceedingly careless in keeping their different kinds of materials separated. Unless this is done it is impossible to make a uniform mixture of the various materials and provision for the piling in separate and convenient places of the different materials should always be made before they are delivered. This is a very important consideration and lack of attention to it will not only hamper the execution of the work but impair its quality as well. It is necessary and advisable to impress on all the dealers furnishing raw materials the necessity of a uniform supply. This is particularly the case with sand dealers, who are often small men who have been accustomed to supply sand to builders and parties requiring it in small amounts. Almost invariably, men of this type will not realize the great difference which a, to them, small variation in the mesh composition of the sand will make to the paving contractor.

12. Specifications for Materials

The following specifications for materials used in sheet-asphalt pavements were adopted in 1916 by the Am. Soc. Mun. Imp. At the conclusion of the specifications comments and explanations pertaining to several sections of the specifications have been appended.

"2. The materials used must comply with the requirements of these specifications and be suitable for use upon the street or streets to be paved. They shall be mixed in definite proportions by weight, depending upon their character, and the traffic upon the street, and such materials and proportions must be satisfactory to the Engineer.

"3. **Methods of Testing.** All tests herein specified must be conducted according to official methods on file in the office of the Engineer. All penetrations at 25° C (77° F) are expressed in hundredths of a centimeter and are to be taken, except where otherwise specified, with a No. 2 needle acting for 5 sec without appreciable friction under a total weight of 100 g.

"4. **Refined Asphalts.** The refined asphalts admitted under these specifications shall be prepared from a natural mineral bitumen, either solid or liquid, or from combinations thereof, by such methods of refining as will produce a product complying with the requirements hereinafter given.

"The preparation and refining of all asphalts admitted under these specifications shall be subject to such inspection at the paving plants and refineries as the Engineer may direct. Every refined asphalt admitted under these specifications, if required by the Engineer, shall be equal in quality to the recognized standard for its particular kind or type of asphalt. If desired, the Contractor may use an asphalt cement prepared at the refinery. To be acceptable this asphalt cement must comply with the foregoing general requirements for refined asphalt, as well as requirements a, b, c, d, and e for asphalt cement.

"Asphalt obtained by the refining of natural liquid bitumens shall not be reduced in the refining process to a penetration at 25° C (77° F) of less than 30.

"All refined asphalts admitted under these specifications must comply with the following requirements.

a. All shipments of refined asphalt of any one kind shall have the batch number plainly marked on each package or container and shall be uniform in consistency

and composition and shall not vary from maximum to minimum more than 15 points in penetration at 25° C (77° F).

b. Ninety-eight and one-half per cent of the total bitumen of all refined asphalts shall be soluble in carbon tetrachloride.

c. When made into an asphalt cement by the use of such materials and methods as are described in these specifications, they must produce an asphalt cement complying with all the requirements elsewhere set forth herein for asphalt cements.

"5. **Fluxes.** These shall be the residues obtained by the distillation of paraffin, asphaltic, or semiasphaltic petroleums. They shall be of such character that they will combine with the asphalt to be used to form an acceptable and approved asphalt cement complying with the requirements of these specifications. All residuums must pass the following general tests:

a. They must have a penetration greater than 350 with a No. 2 needle at 25° C (77° F) under a 50 g weight for 1 sec.

b. They shall have a specific gravity at 25° C (77° F) between 0.92 and 1.02.

c. When 20 g of the flux is heated for 5 hr at 163° C (325° F) in a tin box, 2¼ in in diameter and ¾ in deep, after the manner officially prescribed, the loss shall not exceed 5% by weight and the residue left after such heating shall flow at 25° C (77° F).

d. They shall not flash below 177° C (350° F) when tested in a closed oil tester.

e. They shall be soluble in carbon tetrachloride to the extent of not less than 99%.

"6. **Binder Stone.** This shall be clean, hard, broken stone, free from any particles that have been weathered, or are soft. If the stone does not contain the proper amount of material passing the ½-in screen, the deficiency may be made up by the addition of gravel or sand. Ninety-five percent of the binder aggregate shall pass a screen having circular openings whose diameter shall be three-fourths the thickness of the binder course to be laid. The remaining 5% shall not exceed in their largest dimension the thickness of the binder course to be laid. The binder aggregate shall be so graded from coarse to fine as to have the following mesh composition, sieves to be used in the order named:

Passing		Total passing
10-mesh	15 to 35%	½-in.....35 to 85%
½-in circular opening and retained on 10-mesh	20 to 50%	

"The above limits as to mesh composition are intended to provide for such permissible variations as may be rendered necessary by the available sources of supply and the character of the work to be done. The mesh composition and character of the stone may be varied, within the limits above specified, at the discretion of the Engineer, depending upon the kind of asphalt used and the traffic conditions upon the street or streets to be paved.

"7. **Sand.** The sand shall be hard, clean grained and moderately sharp. On sifting it shall have the following mesh composition, sieves to be used in the order named:

Passing		
200-mesh	0 to 5%	
100-mesh and retained on 200-mesh	10 to 25%	Total passing 80-mesh and retained on 200-mesh............20 to 40%
80-mesh and retained on 100-mesh	6 to 20%	
50-mesh and retained on 80-mesh	5 to 40%	
40-mesh and retained on 50-mesh	5 to 30%	
30-mesh and retained on 40-mesh	5 to 25%	Total passing 10-mesh and retained on 40-mesh............12 to 45%
20-mesh and retained on 30-mesh	5 to 15%	
10-mesh and retained on 20-mesh	2 to 10%	
8-mesh and retained on 10-mesh	0 to 5%	

"On very light traffic streets a coarser sand may be used with the approval of the Engineer, but in no case shall a sand be employed that contains less than a total of 15% passing an 80-mesh sieve, such total to contain not more than 5%, calculated on the original sand, passing a 200-mesh sieve, or a mixture of 75% of sand of the character above specified and 25% of stone screenings passing a ¼-in screen and retained on a 10-mesh sieve may be employed.

"The above limits as to mesh composition are intended to provide for such permissible variations as may be rendered necessary by the available sources of supply. and the character of the work to be done, it being understood that the coarser permissible grading is intended for use on light and medium traffic streets only, and that

for heavy traffic streets, the finer grading shall be required. The mesh composition and character of the sand shall be varied, within the limits above specified by the Engineer depending upon the kind of asphalt used and the traffic conditions upon the street or streets to be paved.

"**Filler.** This shall be thoroly dry limestone dust or Portland cement, the whole of which shall pass a 30-mesh sieve and at least 66% of which shall pass a 200-mesh sieve. The surface mixture shall contain from 6 to 20% of this filler, depending upon the kind of sand and asphalt used and the traffic conditions upon the street or streets to be paved.

"**8. Samples.** One pound samples of the refined asphalt, petroleum flux and asphalt cement that the Contractor proposes to use in his work, together with a statement as to the source, character and proportions of the materials composing them, must be handed in with his bid and no contract shall be awarded to any bidder whose samples do not comply in every respect with these specifications. No asphalt other than that specified in his bid shall be used by any Contractor except with the written consent of the Engineer and provided that it complies in all respects with the requirements of these specifications.

"In addition to the samples submitted with the bid, other samples taken from and actually representative of the refined asphalt, petroleum flux, sand filler and binder stone to be used upon the street shall be submitted to the Engineer before the use of such materials in the work is permitted. Except at his option, no work on binder or surface shall be commenced within 3 weeks from the date when such samples were submitted and in no case shall they be used until they have been examined and approved by him. Whenever, during the course of the work, new deliveries of paving materials are received by the Contractor, samples of these shall at once be submitted to the Engineer and their use in the work will not be permitted until they have been examined and approved by him.

"**9. Asphalt Cement Preparation.** The asphalt cement shall be composed of refined asphalt, or asphalts and flux, where flux is required, of the character elsewhere herein specified and must be of a suitable degree of penetration.

"The proper proportions of the refined asphalt, or asphalts, and flux shall be melted together at a temperature between 135° and 204° C (275° and 400° F) and thoroly agitated by suitable appliances until they are completely blended into a homogeneous asphalt cement. Thereafter the asphalt cement must not be heated to a temperature exceeding 177° C (350° F). If the asphalt cement contains material that will separate by subsidence while it is in a molten condition, it must be thoroly agitated before drawing from storage and while in use in the supply kettles. Excessive agitation with steam or air which will injure the cement must not be used.

"The refined asphalt or asphalts and flux comprising the asphalt cement shall, when required, be weighed separately in the presence of the authorized inspectors or agents of the Engineer.

"**10. Asphalt Cement Requirements.** The asphalt cement shall comply with the following requirements:

a. It shall be thoroly homogeneous.

b. It shall have a penetration at 25° C (77° F) of from 30 to 55 for heavy traffic streets and 55 to 85 for light traffic streets depending upon the sand and asphalt used and the local climatic conditions.

c. It shall not flash below 177° C (350° F) when tested in a closed oil tester.

d. When 20 g of the asphalt is heated for 5 hr at 163° C (325° F) in a tin box, 2½ in in diameter and ¾ in deep, after the manner officially prescribed, the loss shall not exceed 5% by weight and the penetration at 25° C (77° F) of the residue left after such heating must not be less than one-half the penetration at 25° C (77° F) of the original sample before heating.

e. Either the asphalt cement or its pure bitumen when made into a briquette, Dow mold, shall, at 50 penetration, 25° C (77° F), have a ductility of not less than 30 cm at 25° C (77° F); the two ends of the briquette to be pulled apart at the uniform rate of 5 cm per min.

When the asphalt cement as used has a penetration other than 50 at 25° C (77° F) an increased ductility of 2 cm will be required for every 5 points in penetration above 50 penetration and a corresponding allowance will be made below 50 penetration."

Comments and Explanations of sections of the Am. Soc. Mun. Imp. 1916 specifications.

Sections 4 and 10. Under these specifications asphalt prepared by refining hard native bitumens, soft native bitumens and asphaltic petroleums or combinations thereof are admitted provided that the refining processes are carried on in such a way as not to injure the materials and provided that the finished product is or is capable of producing an asphalt cement possessing the essential qualities for paving work.

Section 4, Paragraph 2. Different asphalts possess different properties in varying degrees and it is the sum of these properties which determines their fitness for paving work. In establishing a minimum permissible standard for each essential quality it is obvious that any one asphalt will probably exceed this minimum in one or more instances. It is not intended to encourage the production of an asphalt which shall only just pass the minimum requirements in every respect. Hence the clause in the second paragraph of section 4 requiring that all asphalts "shall be equal in quality to the recognized standard for its particular kind or type of asphalt" and to insure this, provision is made for inspection at the refinery. Asphalts made from a certain crude might be so treated as to injure them materially and yet just bring them within the minimum requirements.

Section 4, Clause a. Comparative uniformity in consistency or penetration is very desirable as tending to produce uniformity in the asphalt cement prepared at the paving plant, as once the requisite amount of flux is determined, it will not have to be changed materially. Marking the barrels with batch numbers makes it possible to sample the contents of a car satisfactorily without opening an excessive number of barrels. Without this precaution, three or four samples taken from a car containing barrels from several batches might all come from the same batch.

Section 4, Paragraph 3 and Clause b. Overheating or too prolonged heating is herein guarded against.

Section 5. This provides generally for the use of a suitable flux and one which, regardless of its composition or characteristics, must combine with the refined asphalt used to produce an acceptable asphalt cement. Fluxes might pass all the tests prescribed and yet be unsuitable for use with a given asphalt even tho they were satisfactory with other asphalts.

Section 5, Clause a. This provides for a liquid flux because without this provision certain solid asphalts might be claimed to be fluxes and therefore exempted from the requirements governing solid asphalts.

Section 5, Clause b. This prevents the use of too light or too heavy a flux.

Section 5, Clause c. This limits the percentage of light oils and the hardening due to their evaporation. A flux which hardened unduly under heat would produce an asphalt cement which would harden rapidly in the kettles and in the pavement after it was laid.

Section 5, Clause d. This insures a flux which will not produce dangerous quantities of inflammable vapor when used in the plant.

Section 5, Clause e. To a certain extent this clause is intended to prevent overheating to such an extent as to decompose the flux or crack it to an undesirable degree.

Section 6. This specifies the kind and size of stone to be used for binder and would appear to call for no detailed comment other than that which already has been given under BINDER STONE.

Section 7. This describes the sand. The limits given are sufficiently wide to provide for both light and heavy traffic mixtures. These limits are of course wider than should be applied to any particular set of conditions. Under the provisions of this section the engineer may and should narrow the limits to suit the conditions prevailing upon the streets to be paved and the available local material. This is fully discussed under SAND.

Section 7, Paragraph 4. The provisions of this section are in accord with the principles discussed under FILLER.

Section 8. This is an important section, more especially where it relates to the samples to be taken from the materials which are actually to be used in the work and have been assembled for that purpose. Bidding samples are required of only the refined asphalt, flux and asphalt cement and these of course must comply with the requirements of the specifications in order to insure consideration of the bid. Bids

are frequently made a long time in advance of the work and it often happens that the materials supplied to the contractor are not exactly the same as his bidding samples. When the variation is slight, this is not an important matter, but he should not be permitted to change the character and kind of the materials without the knowledge and consent of the engineer. Samples of sand and stone, if obtained from dealers, frequently differ greatly from actual deliveries made by them. For this reason, samples should be taken from actual deliveries before too great an amount has accumulated at the plant. If the samples are unsatisfactory, rejection will then not work great hardship to the contractor. It is often difficult to obtain satisfactory sand and it may be necessary to prospect for and open new pits. This takes considerable time and unless the samples are secured sufficiently in advance, laying of the binder and surface may be delayed, which in many cases is very undesirable. Contractors are prone to delay the furnishing of working samples until the last moment, hence the provisions contained in this section as to the time for handing in these samples.

Section 9. This describes the preparation of the asphalt cement and involves principles previously discussed at length. The provision for a maximum temperature of 204° C (400° F) during fluxing is to provide for those asphalts which are difficultly soluble in the flux. Once the solution is complete, the maximum temperature is limited to 177° C (350° F).

Section 10, Clause a. This clause is intended to insure that the flux and refined asphalt are in complete solution and that any finely divided mineral matter which the asphalt cement may contain is evenly and uniformly distributed thruout its mass.

Section 10, Clause b. This provides that the asphalt cement shall be of a suitable consistency (penetration) for the use intended. The reasons for varying the penetration in accordance with the traffic are fully discussed under THEORY OF SHEET-ASPHALT PAVEMENTS.

Section 10, Clause c. This insures an asphalt cement which will not produce dangerous quantities of inflammable vapor when used in the plant and also limits the amount of light oils which it may contain.

Section 10, Clause d. This also limits the percentage of light oils which the asphalt cement may contain and prevents the use of an asphalt cement which would harden too rapidly in the kettles and in the pavement. The test described herein indicates the extent to which bitumens in the course of time lose their more volatile hydrocarbon constituents and the hardening resulting from volatilization and chemical change. It may be considered as an accelerated exposure test and the limits given have proven safe in actual practice.

Section 10, Clause e. The necessity for ducility has been fully discussed under ASPHALT CEMENT and THEORY. The test described herein measures approximately the cementing value of a bitumen but is not necessarily a measure of the relative cementing value of different bituminous materials, or the same bituminous material at different temperatures. With the same bitumen an increase in penetration (softening) results in an increased ductility provided a suitable softening agent is used. The introduction of mineral matter into a bitumen frequently reduces its ductility. For these reasons the minimum allowable ductility is stated at 50 penetration at a standard temperature 25° C (77° F), and if an impure asphalt cement, in the state in which it is used, falls below the standard of ductility, the pure bitumen which it contains must be extracted and tested before the material is condemned. If the pure bitumen meets the test the material is acceptable so far as this clause is concerned. Asphalt cements as used are frequently above or below 50 penetration. An approximate correction allowance is therefore established permitting the testing of such asphalt cements at the penetration at which they are to be used.

CONSTRUCTION

13. Plant and Tools

Operations. In the manufacture of bituminous pavements by the mixing method, three distinct operations are involved; viz,

1. Drying and heating of the mineral aggregate,
2. Preparation and heating of the asphalt cement or bituminous cementing materials,

3. Mixing the hot mineral aggregate with the hot asphalt cement.

In a properly designed plant, the machinery for carrying out each of these operations must be capable of handling sufficient material to insure the required output. Take, for instance, a sheet-asphalt plant having a capacity of 2000 sq yd of 2-in wearing surface per working day of 10 hr. A sq yd of surface mixture 2 in thick when compressed will average 200 lb in weight. The total weight of the output will therefore be 2000 × 200 or 400 000 lb. This mixture will consist approximately of: Sand, 79%; dust or filler, 10%; bitumen, 11%.

The different portions of the plant must, therefore, be capable of handling the following quantities of material:

Drier,	316 000 lb	= 126.4 cu yd sand,
Melting tanks,	44 000 lb	= 22 tons pure bitumen,
Mixer,	400 000 lb	= 200 tons surface mixture.

In order to more fully appreciate just what is required of an asphalt plant, it will be necessary to consider briefly the kind of raw materials used in it and the conditions under which they are handled.

Sand. Depending upon the temperature of the air, this requires to be heated to between 177° and 204° C (350° and 400° F). While actual paving work is not usually carried on in rainy weather it is nevertheless frequently necessary to run very wet sand or stone thru the drier owing to its having been exposed to the weather or because freshly dredged sand is being used. Unless ample drier capacity is provided, therefore, the output of the plant when using wet sand will be greatly reduced. Many pavements are laid late in the fall or in early winter and under these conditions much greater drier capacity will be required than in warm weather, if the maximum output of the plant is to be maintained.

Asphalt Cement. This is ordinarily made by mixing together the requisite proportions of refined asphalt and heavy fluxing oil, altho it is sometimes purchased of the proper consistency for use. The asphalt cements in common use contain from 60 to 100% of pure bitumen. In order to produce a pavement containing a fixed percentage of bitumen it is necessary to use much more of an impure asphalt cement than of a pure one. Plants designed for use with impure asphalt cements will therefore require much greater melting kettle capacity than if pure asphalt cements were to be employed. There are a number of plants upon the market which, while admirably designed for use with pure asphalts, have far too limited a melting tank capacity to permit of anything like their normal output being maintained if an impure asphalt is used in them.

Mixture. The capacity of the mixer in a plant of the size under discussion is usually rated at 9 cu ft. This means that the batch dumped into it contains 9 cu ft of sand plus the other ingredients. Dry hot sand will average about 95 lb per cu ft. In accordance with the formula previously given and assuming that a pure asphalt cement is being used, each batch would therefore consist of the following: Sand, 855 lb; filler, 108 lb; asphalt cement, 119 lb; total weight, 1082 lb. It will take 370 batches of this size to turn out the required amount of surface mixture. In a 10 hr working day this means 37 batches per hr or one batch every 1.62 min. Not less than one full minute with a mixer speed of 60 to 80 rev per min should be allowed for actually mixing each batch of surface mixture. This leaves a total of only 37 sec in which the mixer must be charged with the various ingredients and the finished mixture dumped into the wagons. With a well organized gang and a properly working plant, 20 sec is all that is neces-

sary, but it can readily be seen that this is one of the points where seconds count. The mixer capacity of a plant is usually figured very closely and this makes it more than ever necessary that the melting tank and drier capacity should be ample to furnish a continuous and uninterrupted supply of hot sand and asphalt cement, as it is almost impossible to make up for delays at the mixer. Increasing the size of the mixer would at first appear to be a very simple way of providing against mishaps and this is quite commonly done in stationary plants. Increasing the size of the batch, however, means increasing the size of the engine, and this, in turn, means increased boiler capacity, both of which are very serious considerations in a portable plant. For this reason the average size mixer on a portable plant does not exceed 9 cu ft. Many foremen when trying for a record run will reduce the time of mixing their batches, but this is a practice which should never be permitted, as an insufficiently mixed pavement can not be expected to last.

The question of maintaining a maximum output is more serious in a paving plant than in many other lines of manufacture. To a partial extent, the unit cost of a reduced output may be kept down by employing a suitable number of laborers at the plant. The street gang, however, must be maintained at full efficiency and as they are trained men, they are usually kept under full pay. A gang organized in the morning to take care of 2000 sq yd of pavement can not be reduced on short notice so that they can lay a total of only 1200 sq yd during the day at the same unit cost.

A consideration of just what is required of the various parts of a plant follows:

Drying and Heating Machinery. This may be subdivided into: Cold sand elevator and drier; hot sand elevator; hot sand storage bin and screen.

Drier and Cold Sand Elevator. In the ordinary revolving drum drier the drum shells are made of $\frac{7}{16}$-in steel plate with butt strapped joints and are carried at one end by a four-armed spider and at the other end by a head, both of cast iron. The bearing at the hot sand end takes the thrust, being grooved similar to a propeller-shaft bearing and the cap is cored to form a water jacket, by means of which the bearing box can be kept cool. Sheet-steel shelves are rivetted the entire length of the interior of the drum, which give additional heating surface and constantly stir the sand. The combustion gases pass along under the drum in thru the discharge opening, back thru the interior, coming in contact with the falling sand and finally pass out thru the cold sand chute to the fan. In a permanent setting the drums are supported on steel work which is independent of the brick side walls, hence the drums expand and contract without affecting the brick work, and the latter is not subjected to vibration. In a portable setting, the ends are the same as in the permanent setting. The sides are made of steel plate lined with fire brick. The roof consists of two steel plates, the inner and heavier one being grooved to conform to the arc of the drum, thus holding the heat against the drum. The outer plate is carried straight across to form a rain shed. The cold sand elevator, which serves to convey the cold sand from the ground or bin to the drier, is usually of the bucket elevator type. In another type of drum the products of combustion pass thru a central cylinder to which are rivetted sheet-steel shelves. They then run thru the drier between the outer and inner drums and finally pass thru the exhaust fan to the stack. The outer shell of the drum is also provided with sheet-steel shelves which are rivetted

to it. There are also direct heat rotary driers of the single shell type in which the hot furnace gases come in direct contact with the material to be dried. They are provided with elevating shelves arranged in substantially the same manner as those in the other two types of driers already described. In still another type of drier, three-quarters of the hot air and gases enter the cylinder by way of hooded inlet openings. The balance enters thru the rear end of the drum. By the admission of cold air thru the sliding doors in the drier setting, the temperature of the heated air and gases toward the rear end is regulated to suit the material as it becomes drier. The lowest temperatures and the least circulation are found at the rear end of the cylinder, where the material is most dry and dusty. All three types of driers or heating drums are continuously revolved and are lower at the discharge end than at the inlet end, thus insuring the gradual passage of the material to be heated from one end to the other. The essential principle involved in drying a sand is to bring the various particles in direct contact with a large volume of hot air which takes off and carries away the moisture. No matter how much heat is applied to the sand, it will not dry it unless ample means are provided for carrying off the moisture which it contains. For this reason, almost all the modern types of driers have induced draught. In the earlier types of drums where this principle was not fully recognized, it was no uncommon thing to have hot sand delivered at the discharge end of the drier in which the space between the grains were filled with steam and when this sand cooled down it was often found to be quite wet.

Hot Sand Elevator and Screen. This is usually of the bucket type and is ordinarily enclosed to prevent loss of heat. It takes the sand from the discharge end of the drier and delivers it thru a revolving screen, which rejects the coarse particles of gravel, etc, to the hot sand storage bin.

Hot Sand Storage Bin. This varies greatly in size and shape and is provided with an overhead revolving rotary screen. The capacity of these bins is ordinarily from 5 to 15 cu yd, and, within reason, the larger they are the better. When using a very wet or very cold sand that is difficult to dry and heat to the proper temperature, this bin is sometimes filled over night or before the rest of the plant is started in the morning, thus insuring sufficient sand to keep the mixer running at full capacity. Very frequently the temperature of the sand delivered by the drier varies considerably from time to time but this equalizes itself to some extent in a good sized storage bin. When the sand is taken directly from the drier, much of it will often have to be dumped and discarded as being entirely too hot or too cold. The importance of a storage bin of ample size can not be too strongly emphasized.

Melting Equipment. This includes: Asphalt elevator; flux tank; melting tanks; draw-off tanks.

Asphalt Elevator. This is employed to convey the refined asphalt, either in barrels or broken up, to the melting tanks.

Flux Tank. This holds a supply of the heavy oil or flux used to soften the refined asphalt to the proper consistency for use. It is usually provided with steam coils to keep the contents fluid and should be equipped with a measuring gauge so that the quantity drawn off from it may be accurately measured. The flux is usually pumped from it directly to the melting tank, altho it is sometimes pumped into a smaller tank set on a scale so that the amount used may be weighed or more accurately measured than is possible in a large tank.

Melting Tanks. These vary considerably in size but average about 10 tons capacity. They are heated either by direct fire or by steam coils, and, where impure asphalts are used, must be provided with suitable agitators to keep the mineral matter in suspension and prevent it from coking on the bottom of the tanks, and, also, where draw-off tanks are not used, to insure a supply of asphalt cement of uniform purity to the mixer. This is a matter of very great importance, as shown by the following: Assume that an asphalt cement is being used containing 70% of bitumen and 30% of finely divided mineral matter that will settle to the bottom unless constantly and thoroly agitated. If the agitation is insufficient the upper portion of the tank may easily contain an asphalt cement carrying 80% of bitumen while in the lower portion the bitumen contents may fall to 60% of bitumen or less. The formula for the mixture is set on the assumption that the asphalt cement contains 70% of bitumen and in the ordinary method of procedure these proportions would be adhered to thruout the day's run. Assuming that the formula used was: Sand, 800 lb; dust, 100 lb; asphalt cement, 150 lb; total weight, 1050 lb. An 80% asphalt cement would give a mixture containing 11.4% bitumen, a 70% asphalt cement, one containing 10.0%, and a 60% asphalt cement, one containing 8.6%, or a variation of 2.8% of bitumen in the composition of the mixture. Ordinarily a mixture which requires 10% of bitumen to make a good pavement would be dangerously low in bitumen if only 8.6% of bitumen were put into it. Occasionally a crude attempt is made to roughly provide for this by putting in 5 or 10 lb more asphalt cement when drawing from the bottom of the kettle, but this, besides being mere guess work, is totally insufficient, as in the case under consideration it would require 180 lb or 30 lb more of 60% asphalt cement to bring the bitumen contents of the mixture up to the desired 10%. When using hard asphalts of high melting point which can be broken up into small pieces, a melting tank provided with steam coils presents many advantages. The heat comes directly into contact with a larger number of pieces of asphalt and the contents of the tank are more quickly melted and with less danger of burning than when direct fire heating is employed. The pipes should be extra heavy and continuous; that is, without joints, to minimize the danger from leaks which would cause foaming and overflow of the asphalt cement. When softer and more readily melted asphalts are used that in hot weather are impossible to break up into small pieces, the advantages of steam melting are not so apparent. The large pieces of asphalt when carelessly dumped into the tank are liable to bend or break the coils, unless they are protected by a strong grid, and the melting is easily and quickly accomplished without danger of burning by direct heat. Where steam coils are used, larger boiler capacity must be provided and the best type of mechanical agitators can not be installed owing to the obstruction offered by the coils. Agitation by means of steam or air jets must be resorted to and these harden up the asphalt cement much more than the mechanical type of agitators. Mechanical agitators usually consist of paddles attached to a revolving horizontal shaft having a very small clearance between the paddles and the bottom and sides of the tank. Mechanical agitators, if placed in the melting tanks, are liable to be broken by careless charging of large lumps of asphalt and for this reason many plants are provided with a drawing off tank.

Drawing-Off Tanks are ordinarily of the same capacity as the melting tank. As soon as the charge in the melting tank is melted, it is trans-

ferred to the draw-off tank, which is provided with an agitator and means for heating it and its contents kept thoroly mixed. With most pure asphalts little or no mixing is required and the flux combines so readily with them that a small air jet or a slight agitation with a wooden paddle is all that is necessary. With such asphalts a few hours is sufficient to melt and thoroly incorporate the flux with them, whereas with others from 10 to 12 hr in the melting tanks is absolutely essential to insure proper and uniform results. Some draw-off tanks are provided with air-tight covers and the melted asphalt cement in them is blown over thru steam-jacketed pipes by air pressure directly to the mixer. In others a pneumatic lift is employed consisting of a small air-tight tank which is filled from time to time as necessary and from which the hot asphalt cement is delivered to the mixer by means of air pressure when desired. In some plants pneumatic asphalt lifts are used as a substitute for drawing-off tanks. These are provided with a tank of small capacity which is automatically filled from time to time from the melting tank. The asphalt cement flows by gravity into the lift. When the lift has been filled in this manner, the air cock is opened to pressure fróm the air tank; a check valve in the inlet pipe closes, preventing the cement from running back to the tank, and it is then forced up the vertical outlet pipe over to the asphalt cement bucket. All asphalt piping is steam jacketed.

Mixing Machinery. This may be subdivided into: Sand measuring box; dust measuring box, bin and elevator; asphalt cement bucket; mixer.

Sand Measuring Box. This is placed directly under the hot sand bin and in the older types of plants the sand was measured by volume. The box, which was open at the top and rectangular in shape, was hung on trunnions, which allowed its contents to be dumped into the mixer. It was filled a little more than full and struck off with a straight-edge, thus insuring the use of a fairly uniform quantity of sand. Other types are enclosed and fixed, and when full the sand spouts out of a small hole in the filling chute. The best type of box, however, is the open one provided with a beam scale and in which a definite number of pounds of sand is placed at each filling. In an open type box the temperature of the sand is readily tested as often as necessary and if hung on trunnions the sand when too hot or too cold may be dumped on the platform and does not have to be discharged into the mixer and then dumped, which latter proceeding usually necessitates pulling out the wagon which stands under the mixer ready to receive its contents of finished surface mixture. Changes in the mixture and the weight per cubic foot of different kinds of sands can also be much more readily made and determined than with the other types of boxes.

Dust Measuring Box, Bin and Elevator. A sufficient supply of dry dust must also be provided for at the mixer. Some plants have dust elevators and bins and measuring boxes designed on the same lines as the similar devices for handling sand. In others a bin is provided on the floor of the mixing platform and the dust is measured into pails whose capacity has been ascertained beforehand and then dumped by hand either into the sand box or the mixer. The dust is used cold and as only a small proportion of it enters into the composition of the pavement, the storage facilities are on a much smaller scale than those provided for sand. In some cases the dust is weighed directly into the sand measuring box which is provided with a double beam scale for this purpose.

Asphalt Cement Bucket. This should preferably be provided with a beam scale similar to the sand measuring box. A double beam with a

separate weight for the tare is to be recommended, as the accumulation of asphalt cement in the bucket changes the tare from time to time. Some plants still use a measuring gauge, but this is not nearly as accurate as a scale. This bucket is usually suspended on trunnions by means of which its contents are readily dumped into the mixer.

Mixer. This is a plain or steam jacketed iron box provided with two horizontal shafts to which blades are attached. These blades have a pitch resembling those on a propeller and when in motion throw the mixture from the sides and ends of the box toward the middle. They are usually run at from 60 to 80 rev per min. The blades are detachable so that worn ones may be readily replaced and the shafts should be arranged so that they may be easily removed from the box. This permits readily changing without undue delay to a new set of shafts in which the blades are not set so closely together. This is a necessary provision when running coarse stone or binder mixture alternately with surface mixture. The box of the mixer is provided with a dumping slide on the bottom by means of which its contents, after mixing, may be quickly discharged into a wagon waiting below.

Portable and Semi-Portable Plants. The necessity for building plants which were capable of a large daily output and which could at the same time be moved from place to place without undue expense led first to the development of the so-called semi-portable plant, and, secondly, to the development of the railway plant.

Road Plants and Road Machinery. In modern road building where bituminous roads are constructed by the mixing method, it has become necessary to evolve yet another type of plant which may be moved from place to place along country highways when railroad transportation is out of the question. In some of these plants all the machinery has been placed on one unit; in others, two have been employed, and in still others, the plant has been subdivided into three units. Any substantial departure from standard sheet-asphalt practice and design in them should however be viewed with suspicion, as, regardless of the plant, the principle involved in the manufacture of paving mixtures remains or should remain the same if successful pavements are to be laid and they must not be sacrificed for the sake of portability.

Tools. The special tools used in the asphalt industry are: Wagons, shovels, rakes, tampers, smoothers, sandals, asphalt cutters, fire wagons, surface heaters, and rollers.

Wagons. While ordinary dump carts or wagons are sometimes used, a special form of dumping wagon which is cut under so that it may be readily turned in a narrow street is desirable and is usually employed by all the large paving companies. They should preferably be lined with sheet iron to facilitate the removal of the mixture from them. A body constructed entirely of iron would be undesirable because during long hauls in cold weather the mixture would lose too much of its heat by radiation. Where circumstances will permit, motor trucks can be used to advantage, as work can be carried on at much greater distances from the mixing plant.

Shovels. These are of the ordinary short-handled, square-ended variety of contractor's shovels, but it is desirable to have the metal shank which takes the handle extend up some distance to prevent the burning of the wood when the shovel is heated in the fire. This heating is necessary in order to prevent the hot surface of binder mixture from adhering to them.

Rakes are extra strong and of a special pattern, having teeth about 3½ in in length and a long shank and metal socket to take the wooden handle and prevent it from being burned off when the rakes are heated.

Tampers are of cast iron with hollow iron handles and the tamping base is either square or rectangular in shape. The tamping face varies in size but is usually from 30 to 40 sq in in area. They are heated and used to compress the pavement around manholes, on joints, along street-car tracks and in gutters and generally in places where the roller can not reach.

Smoothers are of cast iron with hollow iron handles and have a rocker face so that they may be pulled back and forth over the pavement. They vary in dimensions and weight but usually have a face about 6 by 10 in. They are heated and used to smooth and heat joints and close up surfaces which do not close up properly under the roller, more especially in cold windy weather. Where the pavement is to be subjected to very wet conditions, they are sometimes used over the entire surface to bring the bitumen to the surface and close up the pores, thus preventing water from entering them. They should be used with extreme care and only be placed in the hands of highly skilled men, as there is great danger of burning the asphalt cement in the surface by the use of them.

Sandals are usually made of leather and are worn by the rakers and the men who have to walk on the newly laid surface, such as tampers, smoothers and cement sweepers. By their use sharply defined footprints in the hot pavement are avoided and they also serve as a protection to the men's feet and shoes.

Asphalt Cutters are used for cutting back the joints and cutting out portions of the pavement. They may be described as double-bladed axes of peculiar design having a blade shaped more like that of a mattock than an axe.

Fire Wagons are of iron with four wheels and of sufficient size to heat the shovels, rakes, tampers and smoothers used by the street gang. They are sometimes provided with racks from which to hang buckets of asphalt cement used to paint joints and around the edges of manholes, curbs, etc. Wood is preferred to coke or coal as a fuel in them, as the surface of tampers and smoothers are less liable to be pitted by it.

Surface Heaters are of various types and are used to dry foundations or soften old or defective pavements prior to repairing or resurfacing them. They are of three types; those using coke, gasolene or kerosene, and hot air and steam as softening agents. Coke heaters are usually iron fire baskets on four wheels of small diameter so that the bottom of the fire is only a few inches above the pavement. They vary in size, but 3 by 4 ft is about the average. Gasolene or kerosene heaters are of the Perkins or Wells type and have a reservoir containing the fuel. This is forced by air pressure to the burner which is protected by a metal shield which also serves to throw the heat and flame directly down upon the pavement. They are mounted on wheels. Hot air and steam heaters of the Lutz type are portable boilers provided with their own motive power. They force a blast of air and steam down on the pavement under a shield or hood which is 5 by 10 ft in size. They are very rapid in their softening action and are largely employed on resurfacing work. With a single one of these machines, from 500 to 1500 sq yd can be resurfaced in a day. In all three types of machines, heat is usually applied to the surface of the pavement until it has been softened to a depth of approximately 1 in. The softened surface

is then removed by means of rakes and shovels and while the bottom part of the old pavement is still warm new surface mixture is spread over it and rolled and finished in the usual way. In this way the upper portion of an old pavement may be quickly and cheaply removed and covered with an inch of new wearing surface at much less cost than would be involved in the complete renewal of the pavement.

Rollers. In some instances hand rollers are used to give an initial compression to mixtures which will not take a heavy roller while hot. This is sometimes desirable in cold windy weather with certain types of mixtures, to prevent the chilling of the surface and the consequent honeycombing of the pavement which would otherwise result if the heavy roller had to be kept off the surface mixture for a considerable length of time after it had been raked. In the early days of the industry hand rollers were always used to give the initial compression and they were sometimes heated by fire baskets suspended in them. Steam rollers are usually of the tandem type and vary in weight from 2½ to 13 tons, 8 tons being about the average. They should be balanced so that the weight on both sides is the same. Some of them are provided with power steering gear and others are steered by hand. In the very heavy types power steering gear is desirable. Gasolene rollers are undesirable, as they usually reverse with a jerk, which leaves a depression in the pavement which is very difficult to remove. A three-wheeled roller has also been used to a limited extent in England and on the Continent, the three rolls being of the same width and placed directly in line. It is claimed by the makers that with this type of roller there is less tendency to produce waviness in the finished pavement.

14. Methods of Manufacture

Asphalt Cement. Where it is necessary to flux a hard asphalt, care must be taken to see that the flux is free from water; otherwise the contents of the melting tank are liable to boil over and possibly take fire from the fires underneath. The flux as turned out by the manufacturer is usually free from water, but when purchased in large quantities is frequently shipped in tank cars provided with steam coils to facilitate pumping. Storage tanks are usually fitted with steam coils also. Where any leak occurs in these coils, water enters the flux and can only be removed by heating the flux above 100° C (212° F). During this process, copious foaming takes place and unless the tank has a large excess capacity it will foam over. If flux containing water is added to a tank already nearly full of hard asphalt, there will be insufficient room to take care of the foaming and the heat must necessarily be applied very gradually. Under these circumstances it sometimes requires 2 to 3 days to drive off the water and until it is driven off the asphalt cement can not be used. Either the flux should be freed from water in a separate tank or it should be put into the melting tank and the water driven off before any hard asphalt is added. In this way there will be sufficient excess space to accommodate the foam and the heating can proceed much more rapidly. Agitation, preferably with air, will materially assist in driving off the water and reduce the time necessary. The proportions of flux and hard asphalt to be used are usually determined by preliminary laboratory tests or drawn from previous experience with the same materials. Different deliveries of the same kinds of hard asphalt and flux often vary to a certain extent, which will render necessary a departure from the formula decided upon, but this can only be determined accurately by charging a kettle to its normal capacity and

testing the resulting asphalt cement. In laboratory tests on small samples, the conditions of heating and the relative amounts involved and the surface exposed to evaporation always differ from those found in practice. Careful record must always be kept of the weights of both hard asphalt and flux charged into the kettles. The flux is sometimes measured instead of being weighed and its weight calculated from its specific gravity. Assume that an asphalt cement of 55 penetration is desired and that the proportions required, as shown by tests or otherwise, are as follows: Hard asphalt, 100 lb; and flux, 10 lb; and that the charging record was hard asphalt, 20 000 lb, and flux, 2000 lb. Upon testing, the asphalt cement was found to have a penetration at 25° C (77° F) of 50 and the hard asphalt of 30. Evidently 10 lb of flux raised the penetration of 100 lb of hard asphalt 20 points (50 − 30). One pound of flux would therefore raise the penetration of 100 lb of asphalt 2 points (20 ÷ 10). The asphalt in question required to be raised 25 points (55 − 30) in penetration, which would require 12½ lb (25 ÷ 2) of flux per 100 of hard asphalt. The kettle contained 20 000 lb of hard asphalt and therefore should have had added to it 12½ times 20 000 divided by 100 or 2500 lb of flux. As only 2000 lb of flux were used, 500 lb (2500 − 2000) more must be added. Let it now be assumed that under the same conditions the asphalt cement was found to have a penetration of 60 and the hard asphalt of 30. Evidently 10 lb of flux raised the penetration of 100 lb of hard asphalt 30 points (60 − 30). One pound of flux, therefore, raised the penetration of 100 lb of asphalt 3 points (30 ÷ 10). The penetration desired for the asphalt cement was 55 and the penetration of the hard asphalt was 30, hence sufficient flux should have been used to raise the penetration of the hard asphalt 25 (55 − 30) points and this would require 8⅓ lb (25 ÷ 3) of flux for every 100 lb of asphalt. Stated in another way, the asphalt cement should contain 12 lb (100 ÷ 8⅓) of hard asphalt for every pound of flux. The charging record shows that 2000 lb of flux were used, hence 24 000 lb (2000 × 12) of hard asphalt should have been put in the kettle. As only 20 000 lb were put in, it will be necessary to add 4000 lb (24 000 − 20 000) more of hard asphalt. These calculations based on the softening power of the flux are sufficiently accurate for practical purposes but do not hold good over a very wide range. The softening power of 1 lb of flux added to a hard asphalt of 20 penetration will usually be less than the softening power of 1 lb of the same flux added to an asphalt cement of 50 penetration composed of the same asphalt and flux. After the kettle has been charged the heat should be gradually increased until the contents are completely liquefied, after which it should be thoroly agitated until the flux and asphalt are in complete solution. The time required for this depends upon the asphalt and flux used as some asphalts dissolve much more readily than others. The general practice is to charge the kettles at night and keep a slow fire under them, gradually bringing the temperature up to 149° C (300° F) by the morning. Very often the night watchman looks after the fires, or steam, if steam melting is used. Before starting work in the morning the contents of the kettle must be thoroly agitated. No asphalt cement should ever be drawn from a kettle until the contents are completely liquefied and thoroly agitated. If the asphalt used contains a considerable proportion of foreign matter which is liable to settle to the bottom of the kettles, agitation must be kept up while the asphalt cement is in use. Different forms of agitation are employed, mechanical agitation being the best for impure asphalts, such as Trinidad. With pure asphalts

requiring but little agitation, high pressure steam or air may be used, but both of these means of agitation tend to harden the asphalt cement and therefore should not be employed to excess. Steam is more liable to carry off light oils and air is liable to oxidize the asphalt and reduce its ductility. Care must be exercised in using steam agitation to see that no water enters with it into the asphalt cement as this will at once cause dangerous foaming. Some asphalts are more liable to injury from overheating than are others, and under ordinary circumstances it is best to set 149° C (300° F) as the maximum temperature to which the asphalt cement is to be heated. In certain cases, owing to low air temperature, very wet sand, long haul, or insufficient drier capacity, it may be necessary to increase this somewhat in order to turn out the mixture at a sufficiently high temperature to insure its being sufficiently hot when it reaches the work. Under these circumstances it may be permissible to heat the asphalt cement up to a maximum of 177° C (350° F), but this should never be exceeded. Grahamite and some varieties of Cuban asphalt which are very slow to dissolve in the flux may be heated for a short time up to 204° C (400° F) to facilitate solution, but once solution is complete the maximum temperatures previously stated should be adhered to. When work is stopped before the contents of a kettle are used up, the heat should be lowered or entirely withdrawn, depending on the duration of the stoppage. Every kettle of asphalt cement must be tested for penetration before it is put in use, and this also applies to asphalt cement left over from a previous day's run. Where it is suspected that the asphalt cement is hardening very rapidly in the kettles, additional penetration tests should be taken as it is being used up, and, if found necessary, more flux should be added to it from time to time. In such cases thoro agitation for ½ hr after the flux has been added will usually be all that is required to make the asphalt cement fit for use. Some few foremen can tell the penetration of an asphalt cement within three points by chewing it, but this should only be used as a guide and accurate penetration tests should always be taken. Flow tests have also been used to check the penetration of an asphalt cement, reference being had to a standard sample for comparison. Asphalt cements made from different asphalts and the same flux will have quite different flows, however, and this is true also of asphalt cements made from the same asphalt and different fluxes. For this reason the flow test is much less used at the present time than it was formerly, and in every instance requires that a check test be run on a standard sample made from exactly the same materials as the asphalt cement being tested. Wherever asphalt cement is pumped, the pipes and pump should be steam-jacketed and carefully drained when the plant is shut down, otherwise the asphalt cement will solidify in them.

Binder. As previously noted, this is composed of stone or stone and sand and asphalt cement. The preparation of the asphalt cement has already been described. When sand and stone are used, these should be kept in separate piles and should be mixed in the proper proportions in a small pile just in front of the cold sand elevator. In large plants provided with storage bins for raw materials the mixing is sometimes done automatically by means of feeding hoppers delivering on to a conveyor belt. Sufficient heat must be maintained under the drying drum to insure the delivery of the stone at the proper temperature to the stone bin. It is necessary to start the fires under the drier some time in advance of passing stone thru them in order that it shall work efficiently. The temperature

of the stone as it comes from the drier must be tested frequently. If it is too cold the rate of feed should be decreased and the fire increased and this should be reversed if the stone is too hot. By putting the drum fireman in charge of the feeding this can be regulated, but an experienced drum fireman must be employed if temperatures are to be kept uniform. Electrical pyrometers are frequently installed in the boot of the hot sand elevator and their recording dials placed where the drum fireman or feeders can readily see them. The pyrometer readings should be checked up from time to time with a thermometer as they are liable to derangement. The temperatures to which the sand and stone should be heated will vary, depending upon the air temperature, the length of haul, the proportion of sand used in the binder and the kind of asphalt cement employed. In cold weather with a long haul the binder mixture should leave the plant at a higher temperature than in warm weather with a short haul. A close binder, that is, one containing approximately 25% of sand, requires a higher working temperature than a binder composed entirely of comparatively coarse stone. Certain asphalt cements require higher working temperatures than others. The guiding principle should be to use temperatures which will not injure the materials and which will insure the delivery of the binder on the street at the most favorable temperature for laying and working it. Depending upon the different conditions stated, the temperature of the stone or stone and sand when it is put in the mixer should be between 107° C (225° F) and 177° C (350° F), but for any given set of conditions the limit of variation should not exceed 28° C (50° F). A certain drop in temperature always takes place between the boot of the hot sand elevators and the discharge of the storage bin, and this must be determined in each case and allowance made for it when establishing limits for temperatures taken at the boot of the hot sand elevator. Material which is too cold must be dumped and passed thru the heating drums again. Material which is only slightly overheated may be put in the mixer and allowed to cool off by agitation before the asphalt cement is added. When it has cooled down to the proper point the asphalt cement may then be added and the mixing continued in the ordinary way. If it is much too hot it should be dumped and allowed to become cool and again passed thru the drums. Segregation is liable to take place to a considerable extent in mixtures of stone and sand during their passage thru the heating drums and while in the storage bin. In many plants, therefore, the stone and sand after being heated are separated by revolving screens over the storage bins and are then recombined in definite proportions by weight before being put into the mixer. Some years ago the sand and stone entering into each batch were always measured by volume and this was also true of the asphalt cement. Modern practice is to weigh all the ingredients and this is much the better and more accurate way altho many of the older plants still use the volume method. After the various ingredients have been measured or weighed out, they are dumped into the mixer, where they should remain for from ½ to 1 min to insure thoro mixing. A close binder should be mixed for a longer time than is necessary for an open binder and the slower the speed at which the mixing shafts revolve the longer should the mixing period be. From the mixer the binder is discharged into wagons below. If the stone has been heated too hot the contents of the mixer will give off a peculiar blue smoke easily recognizable, and if the heating has been carried to a very high point, 204° to 260° C (400° to 500° F), the asphalt cement will probably take fire, in either case

the mixture should be dumped and discarded. In some cases old asphalt pavements are pulverized and used in place of sand. Where this is done the stone is heated separately and the requisite quantity of cold pulverized pavement is added to it just before it is placed in the mixer. This necessitates heating the stone to a higher temperature than would otherwise be necessary in order to offset the addition of this amount of cold material. The stone and old pavement should be mixed together for sufficient time to equalize their temperatures before adding the asphalt cement. Mixing should be continued until the bitumen is evenly disseminated thru the mass and each particle thoroly coated. Fat spots or accumulations of asphalt cement in the binder must be avoided as these will soften the pavement laid over them. As soon as the plant is shut down, mixer and asphalt cement bucket must be cleaned to prevent excessive accumulation of asphalt cement and binder mixture upon them.

Paint Coat. Where a cheaper form of construction is desired, a paint coat is sometimes substituted for the binder course. It is questionable, however, whether it is suitable for heavy traffic streets and in any case great care must be taken in its preparation and application in order to secure satisfactory results. It usually consists of asphalt or asphalt cement dissolved in gasolene or naphtha. In some cases gas engine distillate, heavy naphtha, or turpentine substitute is used instead of gasolene. Certain asphalts dissolve readily in naphtha and make a paint which will dry with a glossy surface. Other asphalts require the use of a heavier solvent as they are not sufficiently soluble in naphtha to make a glossy paint. Too heavy a solvent should be avoided, as paint made with it will not dry rapidly enough to permit the surface mixture to be laid on it shortly after the paint has been applied. As only comparatively small quantities of the paint are used, it is usually manufactured in a more or less crude way at the paving plants, either in small kettles or in barrels. If melting kettles are used the proper proportion, which varies with the asphalt and solvent used but generally averages about 5 lb of asphalt to 1 gal of naphtha, is melted in the kettle. The fire is then completely quenched and the naphtha is added in gradually increasing quantities, with constant stirring, until the asphalt is completely dissolved and the proper amount of naphtha has been added. If made in a barrel, the barrel is laid on its side and filled about one half its capacity with naphtha. Melted asphalt from a kettle is then poured in thru the bunghole in a fine stream and the mixture thoroly agitated from time to time by rocking the barrel. When the melted asphalt and gasolene first come into contact, the heat of the asphalt causes the gasolene to boil and inflammable vapors are given off which on a still day run along the surface of the ground for a considerable distance. For this reason the whole operation should be conducted not less than 100 ft away from any fire. The bung of the barrel should not be driven in until the solution is complete and has cooled off; otherwise the barrel may be burst by the pressure of the gasolene vapor. The paint when made should be tested before using it to see that it dries with a sufficiently thick glossy film to act as a cementing agent between the foundation and the wearing course. The paint coat when used is usually limited to concrete foundations, which should be quite smooth and have the mortar well flushed to the surface, or to old brick pavements which are being covered with an asphalt wearing surface.

Wearing Course. The first step in the manufacture of the surface mixture is the feeding of the cold sand to the drier. As previously noted

under SAND, it is almost always necessary to mix two or more sands together in order to get the proper grading. To insure a uniform mixture the proportions determined upon must not only be strictly adhered to but the different sands mixed must be reasonably uniform in quality. Deliveries, especially from small dealers who are not accustomed to the requirements of the asphalt business, often vary very greatly and for this reason must be carefully watched and tested. The different kinds of sand used must be kept in separate piles. If they become mixed it is almost impossible to turn out a uniform mixture. The various sands are usually wheeled to a pile just in front of the cold sand elevator and measured by wheelbarrow loads. A certain amount of preliminary mixing should be done by shovels before feeding them to the elevator. In some cases the sands are measured in a box or form as used in concrete. Where the main sand piles are close to the elevator, the sands are sometimes shovelled direct from the piles to the boot of the elevator, count being kept of the number of shovelfuls from each pile. If two sands are being mixed in the proportion of 2 : 1, two men would be placed at one pile and one man at the other pile and each man would be instructed to feed at approximately the same rate. Too much attention can not be paid to the mixing of the sand and frequent sieving tests should be made during the day to see that the desired result is obtained. Dry hot sand is very difficult to sample satisfactorily and for this reason it is preferable, wherever possible, to sample the wet sand being fed to the drums. Where the buckets of the cold sand elevator discharge into the feeding hopper of the drying drum some sand is usually thrown outside of the hopper and gradually accumulates in a small pile on some projecting beam or platform or the ground. By cleaning this away and sampling the accumulation during, say, 15 min, an excellent average of the sand fed thru the drum during that period is obtained. As this sand is usually damp, it can readily be sampled, after which it should be dried and sifted. A very great proportion of inferior pavements are directly traceable to lack of care in the selection and mixing of sands and failure to see that the sand deliveries were uniform and the piles kept separate. Where one of the sands is being used in small proportion, fairly thoro preliminary mixing before feeding to the elevator is essential. The regulation of the temperature of the heated sand is even more essential in a surface mixture than in a binder, as it is the wearing surface that is directly subject to the wear and tear of traffic and to climatic conditions. The temperature to which the sand should be heated is subject to the same considerations as those which govern the temperature of the binder aggregate; that is, as to denseness of mixture, weather conditions, length of haul and kind of asphalt used. Some mixtures rake very much stiffer than do others, due either to the kind of asphalt cement used, its penetration, the character and grading of the sand or the amount and kind of filler used in the mixture. Generally speaking, stiff raking mixtures require to be sent out at a higher temperature than do easy raking ones and the first load sent out in the morning and after the noon shut-down should be as hot as consistent with safety to insure a good joint with the cold material previously laid. Depending upon the above conditions, the permissible temperature limits for the sand as it is delivered to the mixer varies from 121° to 177° C (250° to 350° F), but for any one set of conditions the variation should not exceed 28° C (50° F), and the lower limits would only apply to easy raking and not very dense light traffic mixtures laid in the very hottest summer weather. Sand which is too hot or too

cold should be dumped and fed thru the drums a second time. Where the sand is very wet, mixing it with a certain proportion of dry sand or sand which is still hot will increase the output of the drier. Where the drier capacity is limited and the sand full of moisture it is sometimes necessary to run a considerable proportion of the sand thru the drier twice. The sand and dust for each batch should preferably be weighed out and a weighed amount of asphalt cement added to it in the mixer, altho some plants still adhere to the old method of measuring the various constituents. Once the formula for the mixture has been decided upon, it should be strictly adhered to and careless methods upon the mixing platform should not be tolerated. Each batch should be given a full minute's mixing after all the ingredients have been brought together and a less time for mixing should not be allowed. This is based upon the assumption that the blades of the mixer are in good condition and have a speed of from 65 to 80 rev per min. If the mixer speed is slower than this, the time should be correspondingly increased. In any event the mixing must be continued until all the grains are thoroly and evenly coated with asphalt cement. This is especially important where climatic conditions are severe, more particularly as regards rainfall. The more thoro the coating of each grain with asphalt cement the better will the pavement resist disintegrating influences. Every experienced painter knows the value of thoro rubbing in with a brush if he expects his painted surface to stand exposure. With a trained gang and a well equipped and designed plant, a batch can be turned out in 1½ min and still allow a full minute's mixing. Barring breakdowns or unforeseen delays, a plant should average in a day's run 1 batch every 2 min, but this means that the plant must be in good mechanical condition, the gang well broken in and no delays must occur in loading the wagon, and the temperature of the sand must be kept constantly within the proper limits. It is probably not too much to say that most of the failures in sheet-asphalt pavements have been due to improper sand and methods of manufacture and laying rather than to inferior asphalt. The character of the surface mixture being turned out should be carefully watched and the temperature of each load taken and recorded. In the hands of a trained man the mixture may be very closely regulated by the pat test, which is fully described under the head of inspecting and sampling methods. At a given temperature very small variations of bitumen in the mixture can readily be detected and any considerable variation in the mesh composition is plainly apparent on a careful examination of the smooth surface of the pat. After the mixing is completed the mixture is dumped into carts. In some plants, in order to reduce the time required for loading and overcome slight delays in the arrival of wagons from the street, a hopper similar to the box of the dumping wagon and of sufficient size to accommodate a full wagon load of mixture is placed directly under the mixer. This can be filled while waiting for the arrival of a wagon and its entire contents can be dumped as quickly as a single batch, thus permitting the work of the mixer to proceed uninterruptedly except in the case of serious delays to the wagon service. At the close of work the mixer and asphalt cement bucket should be thoroly cleaned as noted under BINDER.

15. Methods of Laying

Transportation. The hot material is brought to the street in carts, wagons or motor trucks and should be protected from the air while in

transit by canvas covers. With proper protection and suitable wagons, the loss in temperature of a load of hot binder or surface mixture should not exceed 5.6° C (10° F) in 2 hr when the air temperature is above 4° C (40° F). In extremely cold weather the loss will of course be somewhat greater. Besides being uneconomical very small loads are undesirable as they increase the number of joints in the pavement, more especially if they do not arrive on the street at regular intervals. Drivers during a long haul are very apt to wait for each other, which results in several loads reaching the street at about the same time. This, of course, causes a gap between subsequent deliveries. Loads of too large a size are objectionable, especially for surface mixture, as a large mass of material is liable to become so consolidated by the jarring incident to a long haul that it can only be removed from the wagons with great difficulty. In cities having large permanent plants the tendency is to run to maximum sized loads. In smaller towns and where the route of haul is hilly, the smaller sized loads prevail. The average load used thruout the country varies from 2 to 4 tons. The carts should be kept clean and if not provided with iron linings are usually whitewashed or oiled in the inside every day to facilitate the removal of the mixture from them. Two-wheeled carts are usually too small to give satisfac ory service for the reasons previously mentioned. Dumping wagons with a small turning radius are preferable, as they can deliver their loads and get away with little loss of time. The ordinary type of dirt wagon with removable bottom slats for dumping should be avoided, as the mixture cools off rapidly in them during transit and while being dumped and much of it is lost in the dumping process. Many contractors carry their own wagons or wagon bodies with them and hire local teams and running gear. In certain special cases, large quantities of hot mixture have been sent by rail or water for considerable distances. In such cases the mixture on the outside of the load will probably chill to such an extent that it should be discarded. Reheating the partially chilled material from the outside has been resorted to in such cases, but it is very liable to injure the mixture and should not be considered as standard or good practice.

Binder. The surface of the concrete should be dry and swept clean before laying binder upon it. A slight amount of dampness is not objectionable but the surface must be free from pools of water. Upon arrival at the street the load of binder mixture should be dumped on a spot near but outside of that on which it is to be spread. It is then roughly distributed by means of hot shovels over the area to be covered and final distribution is effected by hot rakes, after which it should be rolled with a steam roller of from 5 to 7 tons weight. Those portions of the surface which are not accessible to the roller should be tamped with hot tampers. An open binder of good quality should appear bright and glossy when it reaches the street and each particle of stone should be thoroly and uniformly coated with asphalt cement. If an insufficient amount of asphalt cement has been used, the stone will have a dull appearance, and this will also be the case if the stone has been heated too hot, in which event much of the asphalt cement will run off during transit to the street and may be found in pools in the bottom of the wagon. In either case the binder mixture will be lacking in bond and will probably break up under the roller or by the subsequent passage of wagons over it during the delivery of surface mixture on the work. Close binder containing a considerable proportion of fine material will not have this glossy appearance. When

fat spots showing an excess of asphalt cement are apparent, these must be cut out and replaced with other material. The practice of drying them with limestone dust and hot smoothers is not to be recommended. The mixture should reach the street at a temperature between 93° and 163° C (200° and 325° F), depending upon the composition of the binder and the air temperature. If too cold, it can not be raked and spread evenly or properly compressed under the roller. If too hot, it will be burnt or lacking in bitumen and will not bond together when rolled. Close binder should reach the street at a higher temperature than is advisable or necessary for open binder, as the latter variety is much more prone to lose part of its asphalt cement by draining during transit if the stone is too hot. If the binder is dumped on the spot on which it is to be spread, the bottom of the load will remain where it was dumped and will have been compressed to a certain extent by the weight of the material on top of it. The balance of the load will have been thoroly loosened up by shovelling and raking, whereas that which remains in the place where it was first dumped will only be loosened to a small extent by the rakes. When the entire load has been spread so as to present an even upper surface, that portion on which the load was dumped will be covered with a greater weight of binder mixture, owing to its increased density, than the other portion. When it has all been reduced to a uniform density by rolling, this will result in an uneven surface. This consideration, while important in the case of binder, is much more so when surface mixture is being laid. Concrete is rarely in this country laid to an absolutely true grade. One of the functions of the binder course is to fill in the depressions in the concrete and bring it up to an even surface parallel to the surface for the finished street. Binder is much cheaper than surface mixture and it is therefore to the interest of the contractor to see that all depressions are filled with binder and that the binder course, after rolling, is true to grade. This is desirable from another standpoint as well, for a wearing course which is of uniform thickness will wear more evenly and be less subject to displacement than one which varies greatly in thickness. While it is one of the functions of the binder course to fill up minor depressions, this should not be carried too far. Mistakes in grade in laying the concrete which result in depressions several inches in depth over considerable areas should not be filled in with binder, as it will be liable to displacement under traffic. Maximum compression is not as necessary with binder as with surface mixture and the rolling may therefore be delayed for some time after it has been spread, more especially if it is tender or has reached the street at or near the maximum allowable temperature. A good binder mixture properly compressed should not be damaged by hauling sufficient surface mixture over it to cover it. If it breaks up under these conditions it is evidence that it is of poor quality. An open binder in very cold weather is much more liable to be broken up in this way than a close binder and if found necessary, should be protected by planks. Generally speaking, as little hauling as possible should be done over the binder. The surface of the finished binder should be kept clean until it is covered with the wearing course, which should be put down as soon as possible.

Wearing Course. Before the mixture is spread, all dirt must be removed from the surface of the binder course and it is customary to paint the edges of manholes and gutters with a thin coating of asphalt cement to insure adhesion and prevent the water from finding an entrance at these points. This should be done with care, as too much asphalt cement

at any one point will enrich the adjacent surface mixture to an undesirable extent and may make it soft enough to cause shoving. The dumping and spreading of the surface mixture is carried on in the same way as with binder mixture except that more care must be exercised, as this material, when spread and rolled, will form the finished surface of the roadway. Great care must be exercised to thoroly fluff up or loosen the hot material to the same extent thruout and the precaution regarding dumping outside of the spot on which it is to be laid should be strictly observed. The rakers should not be permitted to stand in the hot material while raking it and for this reason no more should be deposited in place by the shovellers at any one time than can be handled by the rakers. They should work it up thoroly with their rakes and with a stiff dense mixture this is often hard labor. The temperature at which the mixture should reach the street depends upon its composition, the air temperature, and the physical characteristics of the materials used. The usual limits are from 110° to 177° C (230° to 350° F), but the lower limit only applies to the less dense light traffic mixtures made with asphalts which become extremely liquid at comparatively low temperatures and which are being laid in the hottest summer weather. Generally speaking, the temperature should be such that the mixture can be raked without too great difficulty, but very dense mixtures are always more or less stiff to rake and different sands, fillers, and asphalts affect this quality to a marked extent. Rounded sands tend to make easy raking mixtures and those containing limestone dust as a filler rake easier than those in which a Portland cement filler is used. Asphalts which do not liquefy readily under heat tend to make stiff raking mixtures. Much can be told concerning a mixture by observing how it acts when dumped from the wagon. Dense, heavy traffic mixtures stand up and the pile partly retains the shape of the wagon. This is true of the best type of heavy traffic mixtures regardless of what asphalt they are made with. Very rich mixtures will always be more or less sloppy and those made with hard asphalt cements will be stiffer than those made with soft asphalt cements. A mixture which appears dry and crumbly under the rake is usually deficient in bitumen and mixtures with normal sand grading and bitumen contents which lack cohesion are usually deficient in filler. Different asphalts have their own peculiar odor, and mixtures made with them frequently exhibit certain peculiarities by which they may be recognised by the trained eye. After the mixture has been spread and raked, it is tamped along gutters and railroad tracks and around manholes and is then rolled with a 5 to 10-ton roller. Some mixtures are quite tender when hot and will not stand a heavy roller without undue displacement which will result in a wavy pavement. In such cases it is sometimes advisable to run the lighter end of the roller over the surface first. When the weather is warm, rolling may be delayed until the mixture has cooled to a sufficient extent to stand the weight of the roller. Where it is cold and windy it is advisable to use a light steam or hand roller to close up the surface and prevent it from chilling on the top to such an extent that the pavement will appear honeycombed. Very hot mixtures will pick up by adhering to the roller, more especially if it is rough from being used on rolling grade. This may be remedied by keeping the rolls wetted with a mixture of kerosene and water. Steam may also be used to wet the rolls but flooding them with fine streams of water which run down on the surface of the hot mixture is not good practice. Kerosene and water is the best and it materially helps to close up the surface of the pavement

under unfavorable conditions. After the preliminary rolling, it is customary to sweep cement or limestone dust over the surface and then complete the rolling. This is often done too close to the freshly raked mixture and the dust is carried on to it by the wind, making it difficult to close it up properly. The dust should be kept off until the rolling is practically finished, as in this way defects in the surface are more easily detected and honeycombed spots may be readily closed up with a smoother. Once the dust has been swept on, it is difficult to detect minor surface imperfections and much more difficult to remedy them with smoothers. Generally speaking, maximum compression should be given to the pavement and this can only be secured by rolling while it is hot. The roller should therefore be run over the mixture just as soon after it is raked as the physical peculiarities of the mixture will allow and the rolling should be kept up as continuously thereafter as possible until maximum compression has been effected and the surface is smooth and true to grade. The more unfavorable the weather conditions, the more important it is that the roller should keep close up to the rakers. Rolling a cold mixture has little or no effect upon it. Rolling should at first be conducted parallel to the curb and each rolling should partially overlap the preceding one. When rolling straight work the point at which the roller stops on the first roll should be 2 or 3 ft distant from the point at which it stops on the second roll. The stopping point on the third roll may coincide with that on the first, and so on. In looking across the rolled work the points of stoppage of the roller will then form a staggered line across the street. A certain amount of mixture rolls up in a wave ahead of the roller and the method of rolling just described prevents the formation of a continuous wave across the street and makes it easier to finish the surface true to grade. Where the width of the street permits, it is customary to roll diagonally the second time and to finish by straight rolling parallel to the curb. Cross rolling is also sometimes used on wide streets and a skilled rollerman will vary his methods in accordance with circumstances and the peculiarities of the mixture. Quick rolling is not desirable, as it does not give the slow kneading action which is essential to thoro compression. Two hundred square yards per hour is about the maximum area of pavement that can be properly rolled by one roller and to do this satisfactorily the roller must be kept in continuous operation. Tampers and smoothers must be used with great care, especially the latter, to avoid burning the mixture, which will cause it to scale or grind out. Under favorable conditions with a suitable mixture the pavement should close up properly under the roller and the smoother only be required on the joints. Under unfavorable conditions it may be necessary to employ smoothers more extensively, but they should not be heated too hot and should be placed in the hands of skilled men. Any defects of surface, such as honeycombing, which requires their use should be given attention immediately after the pavement has received its first rolling, as it is then hot and a very short application of the smoother will suffice to close it up. After it is cold, there is much more danger of burning it, as the heat must be applied for a longer time. When fresh material is laid up against a cold joint it is always advisable to iron it so as to heat the cold pavement sufficiently to insure a perfect bond. In finishing a day's work provision must be made for joining new material to the pavement previously laid. One method is to roll the finished pavement to a feather edge and cut it back so as to expose a fresh surface of the full thickness just before commencing the next day's work. This cut should be bevelled and not ver-

tical. The exposed surface is sometimes lightly painted with asphalt cement but except in very cold weather this is not to be recommended owing to the liability of getting too much asphalt cement at certain points and thus softening the pavement in spots. The more modern and better method of making a joint is to attach a canvas flap to a ¾-in rope and lay this on top of the edge of the wearing course while it is being rolled and roll the pavement under it to its final compression. The rope is allowed to remain in place until just before work starts the next day, when it is removed and the new surface mixture raked upon the fresh surface thus exposed.

16. Inspection of Manufacture and Laying

Inspection of materials and processes during construction work may be subdivided into plant and street inspection.

Plant Inspection. During the progress of the work additional quantities of raw materials will from time to time be delivered to the contractor's plant. These should be sampled and examined in the manner previously described for the preliminary inspection of raw materials and no deliveries should be used in construction work until after they have been examined and tested and found to be in accordance with the requirements of the specifications. Owing to delays in the arrival of shipments this may at times be difficult, if not impossible, but in such cases, if it is inadvisable to shut down the work temporarily, the inspector should make all the tests possible at the plant in order to convince himself that the materials are suitable for the work. If he is able to determine definitely that they are unsuitable, they should, of course, be rejected and work shut down until other suitable material is available. At times it may be necessary for him to assume the responsibility of passing the materials and permitting their use pending an authoritative report from the central testing laboratory. Sometimes there will be but little risk in doing this; under other circumstances it may be advisable to permit the contractor to proceed with his work with the distinct understanding that if the materials are found not to comply with the requirements of the specifications he will take it up. Such an arrangement should only be made in writing and with the consent of the resident or supervising engineer. Where sand is delivered by wagon-load, it will usually be sufficient to take an average sample of the day's deliveries and test it. Where the sand is delivered by rail or barge, the contents of each car or barge should be tested, if possible before unloading it. These instructions apply also to stone and gravel. It is extremely important that deliveries of various grades of stone, sand and gravel should be kept separate.

Generally speaking, the processes involved in the manufacture at the plant of bituminous paving material are: Preliminary mixing and heating of the mineral aggregate; preparation and heating of the asphalt cement or bituminous binder; mixing of the heated mineral aggregate with the hot asphalt cement or bituminous binder.

Preliminary Mixing and Heating of the Mineral Aggregate. The proportions in which the various constituents of the mineral aggregate are to be mixed will, of course, depend upon their character and the specifications under which the work is being carried on. The method of mixing the different ingredients depends somewhat upon the feeding arrangements at the plant and the disposition of the raw materials. In certain large plants the raw materials are stored in bins. In some instances these bins

have automatic feeding devices which deliver the contents of the bins upon a conveyor belt. In such cases the automatic delivery devices should be set at the proper points and during their operation should be watched from time to time in order to see that they are delivering the desired quantity of material. With certain mixtures a mere inspection of the mixed aggregate as it is being fed to the heating drums will enable the inspector to roughly determine whether or not the proportions are being adhered to. With other types of mixtures this is very difficult to regulate by observation at this point. In the majority of instances, plants are not provided with storage bins of the type previously described and the materials are dumped in piles on the ground. These piles are usually arranged so that the material from them can be easily conveyed to the feeding device for the heating drums by means of wheelbarrows or horse slips. Where the mixture consists of sand and stone of various sizes, with a considerable proportion of stone, it is advisable to have the mixture made in a pile adjacent to the feeding device. This can frequently be done satisfactorily by having the requisite number of wheelbarrowfuls of the various ingredients dumped on a certain spot, this pile to be roughly mixed by shovels and then shovelled over into the feeding device. Where a simple mixing of two grades of sand is required, this can frequently be done satisfactorily by building a small box or boot around the bottom of the cold sand elevator and having the fine sand placed on one side and the coarse sand on the other side. One man on each of the two sand piles can then shovel the material into the box above mentioned in accordance with the mixing formula determined upon. Assuming that two parts of coarse sand were required to one part of fine sand, the man on the coarse sand pile would have to throw two shovelfuls of sand into the box to every one shovelful thrown by the man on the fine sand pile. The feeding of the sand thus thrown into the box would be attended to by a third man, who would feed it to the buckets of the elevator by means of a hoe or shovel. Usually the fireman who is in charge of the firing of the heating drums is able to supervise the operation of the feeding gang and see that they feed a properly proportioned mineral aggregate. In mixtures of sand and large sized stone there is liable to be a certain amount of segregation of the material in its passage thru the heating drums. Certain plants are provided with an overhead screen to separate the heated material after it comes from the drums into the various sizes and distribute them into different bins. The material contained in these bins is then drawn out into the measuring box in definite proportions according to weight. This, of course, is the most accurate method of making mixtures involving the use of a large proportion of relatively coarse stone.

The function of the heating drums is to dry and heat the mineral aggregate. Unless ample air circulation is provided for to carry off the moisture in the shape of steam, the drying will not be effectively conducted. It is essential to regulate the rate of feed and the temperature of the heating drums so that the mineral aggregate delivered from them will be dry and at the proper temperature. This operation is usually in charge of the fireman for the heating drums. The most modern plants are provided with a pyrometer inserted in the delivery chute from the heating drums. This pyrometer has a plain or recording dial which is placed at the feeding end of the drums, where it is under the observation of the drum fireman. This makes it easy for him to regulate his fires and the rate of feeding necessary to secure the desired results. Where no pyrometer is inserted, it is neces-

sary for him to test the temperature of the material issuing from the delivery end of the hot sand drums, from time to time, as often as may be required in order to produce satisfactory results. It is a comparatively simple matter to take the temperature of heated sand, but where the mineral aggregate consists of large stone particles, it is a much more difficult and unsatisfactory operation. Certain types of mixing plants are so constructed that it is very difficult to obtain samples of the hot mineral aggregate before it is mixed with the asphalt cement or bituminous binder. Regardless of the difficulty involved, it is good practice to test the temperature of every batch of mineral aggregate in plants of this type before it is mixed with the asphalt cement; otherwise uniform mixtures cannot be expected. Even when the greatest care possible is exercised, there will be considerable variation in the mesh composition and temperature of the mineral aggregate as delivered to the mixer. The permissible variations are usually set forth in the specifications and should be closely observed. Mixtures which vary very greatly in mesh composition will require different amounts of bitumen in order to make the best possible type of mixture. Within ordinary limits, no correction will have to be made for this, but, generally speaking, a mixture containing a large proportion of fine particles will require more bitumen to cover these particles than a mixture containing a smaller proportion of them. This is due to the fact that the finer the mixture the greater the surface area to be covered with bitumen. In order to secure a satisfactory output from the plant, it is absolutely essential that the greatest possible care should be taken in the mixing and heating of the mineral aggregate. In order to insure the proper mixing of the mineral aggregate, it will be necessary from time to time to take samples of the mixed aggregate and sift them for mesh composition. Owing to the extreme difficulty of securing an average sample of hot, dry mineral aggregate, great care must be exercised in selecting the samples. The arrangement of the plant and the kind of mineral aggregate used will determine where and how often these samples should be tested. Samples for test should be obtained from the overflow of the feeding device used in conveying the cold mineral aggregate to the heating drums. This is usually done by a chain and bucket elevator. Where these buckets dump into the chute at the entrance of the drying drums, there is almost always a small overflow which gradually piles up underneath this chute. Assuming this to be the case, the pile can be cleaned off at a given time and the material which accumulates during, say, a ½ hr run can then be sampled, dried and sifted. It is much easier to sample the damp material than it is the dry, and this not only obviates some of the difficulties attendant upon sampling dry material but gives the inspector an average of the material fed into the drums during the ½ hr while the pile was accumulating. In this way much better average results are obtained and the inspector is not liable to be misled by temporary and unimportant lapses in the feeding of the material. In other cases, samples of the hot material are obtained from the delivery end of the drying drums. In such cases a number of samples should be collected and mixed together and the resultant mixture sifted.

Preparation and Heating of the Asphalt Cement or Bituminous Binder. For the preparation of the asphalt cement or bituminous binder, the contractor may purchase a hard bituminous material and add sufficient flux to it to bring it to the proper consistency, or he may purchase an asphalt cement of the proper consistency for use without the addition of any flux.

In the first instance the melting kettles will have to be charged with the proper proportions of flux and hard asphalt to produce the desired asphalt cement. In large plants this is generally done at the close of the day's run. The materials are then kept under a gentle heat during the night and brought up to the desired temperature in the morning. The contents of the kettles are then thoroly agitated in order to insure complete mixing of the different ingredients and a sample from them is taken and tested for penetration before the contents of this kettle are permitted to be used. If it is too hard, more flux will have to be added to it. If it is too soft, more hard asphalt will have to be added to it. After the additions are thoroly melted, the contents of the kettle must be again agitated and tested before using.

In sampling the asphalt cement care must be taken to see that the sample taken really represents the contents of the kettles. Dippers in use in the kettles usually accumulate a considerable amount of dirt and hardened asphalt cement on them. The dipper should be immersed in the melted material for a sufficient length of time to thoroly soften all material adhering to it. It should then be used to stir up the contents of the kettle, which will further assist in cleaning the dipper. If the asphalt cement contains a considerable proportion of mineral matter and there is doubt as to the completeness of the agitation, the dipper should be immersed, bottom upwards, and held in that position until it reaches approximately the center of the kettle. It should then be turned right side up, thus filling it with material obtained approximately from the center of the tank. The sample when obtained should be protected from dust while cooling. Where the asphalt cement is piped to the measuring bucket, samples should only be taken from the delivery spout after sufficient material has passed thru it to insure getting a representative sample. Unless a circulation system is maintained by means of a pump, samples for determining the consistency of the asphalt cement before use should not be drawn from the piping system as it will contain too large a proportion of asphalt cement previously used. Certain asphalts are more difficult to flux than are others and require a longer period of heating. Overheating of the kettles will result in undue hardening of the asphalt cement. If the flux or hard asphalt contains any considerable proportion of water, this will foam very badly in the kettles and frequently cause them to run over. No asphalt cement or bituminous binder should be used until the water has been thoroly removed from it. Where the asphalt cement or bituminous binder contains a considerable proportion of mineral matter or impurities, the contents of the melting kettles must be kept thoroly agitated during the time that they are being drawn upon for use. Suitable mechanical agitation is, perhaps, the most advisable, as in this way the bituminous material is hardened less than if a steam or air blast is used.

Violent agitation with steam or air will very rapidly lower the penetration of the contents of the kettles. In the case of asphalt cements containing a considerable proportion of mineral matter, unless the contents of the kettles are thoroly agitated, the material drawn from them will vary in purity or bitumen content with the result that the portion first taken from the kettle will usually run much higher in bitumen than the portions last taken from it. Assuming that the proportions of the mixture have been set to give the desired quantity of bitumen, based on the average bitumen content of a thoroly mixed kettle, the mixture turned out with the asphalt cement first drawn from the melting kettle will be too rich in bitu-

men and that turned out with the asphalt cement last drawn from the kettle will be too low in bitumen. It is impossible to estimate by observation the changes in weights of asphalt cements necessary to overcome this and the only proper way, therefore, is to so agitate the contents of the melting kettles that the supply of bituminous material drawn from them will be uniform in bitumen content. If for any reason the asphalt cement for a certain day's run is not entirely used up, it should always be tested for penetration before permitting its use on a subsequent day's run. There is, of course, no objection to filling up the balance of the kettle with new material and mixing it thoroly with the portion left from the previous day's run. It should then be considered as a new batch of asphalt cement and tested accordingly. Where hard asphalt and flux are to be melted together, the contractor should never be permitted to draw any material from the melting kettles until their contents have been completely melted and thoroly mixed. Even where the asphalt cement is purchased ready for use, it is not good practice to draw from a kettle containing lumps of unmelted bituminous material. Sufficient melting kettle capacity should be insisted upon to avoid the necessity of doing this. With the exception of the fluxing, the foregoing remarks apply equally to bituminous binders, purchased by the contractor, of the proper consistency for use.

Mixing of the Heated Mineral Aggregate with the Hot Asphalt Cement or Bituminous Binder. It is unquestionably the best practice to weigh out the various ingredients entering into the composition of the finished mixture. Where the different ingredients are measured by volume, much greater variations will occur than when they are measured by weight. If measured by volume, the contents of the various measuring devices must be carefully checked up before the commencement of the work and the gauges set at the proper point. It is advisable to check up the setting of these gauges from time to time to see that they have not been displaced, either intentionally or otherwise. In determining the volume occupied by the desired weights of the different ingredients, it is necessary to measure them at the temperatures and under the conditions used in actual work. In other words, heated dry sand or stone must be filled into the measuring box and the weight of the box when filled to the proper mark determined. This is also true of the bucket or measuring device used for asphalt cement or bituminous binder. If the asphalt cement should contain any water, this will produce foaming and it will be impossible to measure it accurately. If the foaming is at all excessive, it will be impossible to get the required amount of asphalt cement in the ordinary sized measuring bucket. This, by itself, constitutes a sufficient reason for not permitting the use of any asphalt cement which contains water. Where the materials are measured by weight, the tare of the empty measuring devices must be carefully obtained and this tare added to the weight of materials which it is desired to use. In determining the tare of the asphalt cement bucket, it must be borne in mind that after an hour's run there is a considerable accumulation, amounting to several pounds, of asphalt cement on this bucket which will increase its tare above that obtained by weighing the bucket in a perfectly clean state. After once determining the tares and setting the weights or gauges at the proper point, their position on the scale beams or elsewhere should be checked up from time to time to see that they have not been displaced. Occasionally the accumulation of surplus material on the scale platforms of the measuring device for the mineral aggregate will change the tare somewhat. Any such accumulation should be removed as

often as necessary. Unforeseen happenings will occasionally influence the tare of the measuring devices. It was found in one case that the mixture being turned out was entirely too sloppy, altho but a short time before the tare and gross weights of the various ingredients entering into it had been carefully checked up. Upon investigation, it was found that the spout carrying the materials from the hot sand bin had been shifted by the vibration of the machinery so that it rested part of its weight upon the sand box, thus increasing its tare by approximately 200 lb. Each batch of mixture turned out under these conditions, therefore, contained 200 lb too little mineral aggregate, which, of course, accounted for its sloppiness.

The method of mixing varies in different plants. In the larger sized paving plants almost invariably the pug mill mixer, which is recognised as the best type, is used. The blades in this mixer should be examined to see that they are properly set and not unduly worn, thus producing an imperfect mixture at the bottom and sides of the mixer. Ordinarily they should revolve at a speed of from 60 to 80 rev per min. In mixtures of the sheet-asphalt type, one full minute should be allowed for mixing each batch of material. Where the mixture is a comparatively open one consisting largely or entirely of stone, this mixing time may be reduced somewhat. Whatever the type of mixer employed, the proper time for obtaining a thoro mixture should be determined and rigidly adhered to. The temperature of the mineral aggregate delivered to the mixer should be tested as often as may be necessary. This, of course, will depend upon the type of plant used and is a check upon the drum fireman and the feeding operations of the mineral aggregate. The temperature of the asphalt cement in the melting kettles should also be tested as often as may be necessary in order to be certain that it is uniformly maintained at the proper point. Where the type of mixture permits it, frequent pat tests should be taken of the material delivered to the wagons. This test is made by placing a small quantity of the hot mixture upon a sheet of unglazed manila paper, folding over the paper and pressing down upon it with a wooden paddle. After it is thoroly compressed, the paper should be struck a sharp blow with the wooden paddle and then opened for observation. An examination of the surface of the compressed mixture will clearly show to the trained inspector any marked variations in the mesh composition of the mineral aggregate. The depth of stain upon the paper will measure the amount of bitumen which it contains. The richer the mixture in the bitumen the heavier will be the stain. This stain is also influenced by the temperature of the mixture when the pat test is taken. For this reason it is necessary in comparing pats to know exactly the temperature. In obtaining the mixture for the pat test from the wagon, an ordinary mason's trowel will be found convenient. No time should be lost after obtaining the sample in putting it upon the manila paper and making the test; otherwise it will drop very considerably in temperature. The temperature of the material tested can be conveniently determined by inserting a thermometer at the place where the sample was taken from. Convenient and suitable arrangements for making this test should be insisted upon at the plant. This is a most important and valuable guide in the hands of a competent inspector and great attention should be paid to it. In the hands of a trained man, a variation of 0.25% of bitumen can be detected by means of the pat test. This pat test is, of course, not applicable to mixtures consisting chiefly of large particles of stone. The inspector should make careful notes of the various conditions surrounding

the plant. He should take and record at least three times daily the temperatures of the asphalt cement and the mineral aggregate as delivered to the mixer. He should also record his siftings of the mineral aggregate together with the proportions used in making the mixture and of the asphalt cement.

All deliveries of material at the plant should also be noted and a record kept of any tests made on them. These records should be kept on properly designed forms and should state the name of the street on which the mixture is being laid, the kind of mixture and the kind and proportion of the various ingredients entering into it. He should also keep a record of the number of batches turned out from the plant, as this is a valuable aid in checking up the thickness of the pavement laid on the street. At the commencement of the day's run it is customary to send out mixture which is a little hotter than that sent out during the average operations of the plant. This is done in order to enable the workmen on the street to make a close and intimate joint with the pavement laid during the previous day's run. While safe temperature limits should not be exceeded at any time, the maximum limits should be approached in sending out the first few loads in the morning.

Street Inspection. Prior to the delivery of any bituminous materials upon the street, the foundation must be completed in accordance with the requirements of the specifications. The finished foundation must then be swept clean of all dirt, etc. Knowing the type of mixture to be laid and the number of pounds used in each batch and the number of batches per wagon-load, it is usually possible to determine in advance how many square yards should be covered by each wagon-load. The best street foremen, before laying any bituminous material, measure the width of the street and calculate the number of linear feet which should be covered or pulled by each load. A tape is then laid along the curb and a chalk mark made at the point where the raked material from each load should end. Where the foundation is reasonably smooth and in accordance with the contour of the finished pavement, this method is one of the best checks for determining the thickness of pavement laid. Ordinary sheet-asphalt pavement, 2 in thick, will weigh 200 lb per sq yd. Pavements containing a large proportion of good sized stone will vary somewhat from this weight, but the exact weight per square yard can easily be determined during the first day's run.

As soon as the material reaches the street, its temperature should be noted. The hot material should be dumped outside of the spot where it is to be laid in order that all of it will have to be conveyed to its final resting place by means of shovels. This results in a preliminary spreading of material of approximately the same density. Where the load is dumped on the spot on which it is to be spread it will inevitably be tramped upon and certain portions of the heated mixture will receive more compression than others, which will eventually result in an uneven surface to the finished pavement. In certain classes of bituminous mixtures, notably those containing large particles of stone, where the haul is long, the coarser particles may settle to the bottom of the load. If this takes place to any great extent, the load when dumped should be remixed by turning over with hot shovels. In shovelling the hot mixtures into place the shovellers should not dig into the top of the pile but should shovel from the bottom of it, cleaning up the loose material as they go. If this is not done, the lower layer of the pile, in cold weather, will have become chilled by its contact

with the cold foundation and it will be difficult to remove it completely and uneven distribution and compression will result. The mixture, after having been deposited roughly in place by means of shovels, is spread by means of hot rakes. During this operation the rakers should not stand in the hot mixture any more than is necessary. Care should be taken to maintain a uniform and even grade so that there will be no depressions in the finished pavement which will hold water. Some mixtures compress very much more than others, so that it is impossible to establish any definite rule for the depth to which the hot mixture shall be raked.

As soon as possible after raking, the mixture should be rolled. Some mixtures are more tender than others and must be allowed to cool off somewhat before putting the hot roller on them. The hotter the mixture, the greater will be the compression and it is, therefore, desirable to roll it as soon as possible. In very cold weather, especially when a strong wind is blowing, the surface of the mixture will chill quite rapidly. With a tender mixture it is often advisable to use a light hand roller over it as soon as it is raked in order to close up the surface and then follow this with a heavy steam roller as soon as the mixture will bear it. Undue delay in rolling the mixture will result in a more or less honeycombed surface. Depending upon the contour of the street and its width, the rolling should be first done parallel with the curb. This should be followed by diagonal or cross rolling and the final finish of the work by rolling parallel to the curb again. The exact method of handling the roller can usually be left in the hands of the roller engineer if he is an experienced man, as he should know how to smooth up the finish of the pavement better than will the average inspector. At the finish of the day's work it is necessary to leave the pavement in such condition that a proper joint may be made with it when the next day's operations are commenced. There are a number of methods of doing this. Perhaps the best is the rope joint in which a length of rope is laid across the extreme edge of the pavement and rolled into it while hot. When this is taken up very little cutting back will have to be done and the edge will be left in such shape that a satisfactory joint can be made. The practice of painting these joints with hot asphalt cement before laying fresh pavement adjacent to them is to be avoided whenever possible, as the tendency is to put too much asphalt cement on the joint. This asphalt cement is absorbed by the hot mixture and softens it at that point and traffic is liable to displace it. For the same reason the painting of edges of curbs, manholes, etc, should be done with extreme care. A very convenient instrument for determining the depth of the finished pavement is a putty knife with a blade 2 in wide which has been marked across the face of the blade at a point corresponding to the required depth of the pavement. This can easily be inserted in the warm mixture after it has been rolled and the broad point will bridge over any small depressions in the foundation and avoid the recording of a greater depth to the pavement than really exists.

The use of hot smoothers should be avoided whenever possible. With the proper mixture and one which has been rolled while hot, the surface should be entirely closed up. Under unfavorable weather conditions, in order to close up the surface, it may be necessary in certain places to use hot smoothers. Care should be taken to see that these are not too hot; otherwise they will burn the pavement and scaling will eventually result. The inspector on the street should, whenever possible, keep an accurate account of the number of loads delivered. Knowing the number of pounds

of mixture per load and the weight per square yard, he can then check up the yardage which should have been laid with the material delivered on the street if it were raked to the proper thickness.

Inspection of Finished Work. If the inspection at the plant and street during the construction of the pavement has been adequate, the final inspection of the work will be chiefly confined to an examination of the contour and surface of the street. During this examination careful note should be made of whether or not the mixture has been thoroly compressed and is closed up on the surface. Where there has been no inspection during the manufacture and laying of the pavement, or where this inspection has been inadequate, defects will frequently develop in the pavement. Under these circumstances, it becomes necessary to examine the finished work in order to determine the reason for the defects or failures. In an inspection of this sort, careful note should be made of the condition of the surface and its contour. Frequently marked depressions occur where the pavement has been laid over a trench dug just prior to its construction, and in which the back-filling was not properly done. A thoro examination of the street will usually involve the cutting out of numbers of samples of the bituminous surface. These should be carefully marked as to location and a sufficient number of them taken to fairly represent the surface examined. They should be sent to a central laboratory for examination as to the percent of bitumen contained in them, the mesh composition and character of the mineral aggregate and the physical and chemical characteristics of the asphaltic cement used in the pavement. Wherever these samples are cut out, careful note should be made of the depth of the pavement at this point. In many instances it will also be necessary to cut thru the foundation to determine its character and thickness. Laboratory examinations of concrete foundations are usually not very valuable in determining the amount of cement which has been used in them, but a combination of physical and chemical tests of the foundation will often establish satisfactorily whether or not they have been defective. The method of examination used will, of course, have to be varied, depending upon circumstances and the character of the defects which have been developed.

Laboratory Equipment. The plant laboratory should be equipped with a set of standard sieves, 200, 100, 80, 50, 40, 30, 20 and 10-mesh, and a pair of sand scales; a stiff brush for cleaning the sieves, which should preferably be a small one with good, stiff bristles; a sand sampler; a set of screens for testing binder stone, 1/8, 1/4, 1/2 and 1-in; thermometers for use with the penetration machine and for testing the temperature of the paving materials; a penetration machine; a dishpan or other receptacle for holding water at the standard temperature, in which to immerse the asphalt cement samples which are to be tested; two trowels, one 4-in and the other 6-in; a 4-in wall brush; two wooden paddles; a roll of manila paper 12 in wide mounted on a stand provided with a cutting device, two iron pails and a gas or oil stove. This will be sufficient to carry out the simple tests required by the inspector. If chemical analyses are to be made, a much more elaborate equipment will of course be required.

17. Specifications for Construction

The following specifications were adopted in 1916 by the Am. Soc. Mun. Imp. At the conclusion of the specifications, comments and explanations pertaining to several sections of the specifications have been appended.

For sections covering materials, see Art. 12, and for sections covering maintenance, see Art. 22.

"1. General Description. Upon the foundation, prepared and laid as elsewhere herein specified, shall be laid the pavement proper. This shall consist of: (a) A binder course . . . in in thickness when compressed; and (b) an asphalt wearing surface . . . in in thickness when compressed.

"11. Binder, Preparation. The binder shall be composed of stone, or stone and sand, and asphalt cement of the character elsewhere herein specified and mixed in proper proportions. The stone, or stone and sand, and the asphalt cement shall be heated separately to such a temperature as will give, after mixing, a binder of the proper temperature for the materials employed. The stone when used must be at a temperature between 107° and 177° C (225° and 350° F). The asphalt cement and stone shall be thoroly mixed by machinery until a homogeneous mixture is produced in which all the particles are thoroly coated with asphalt cement.

"12. Binder, Laying. The binder mixture prepared in the manner above described shall be brought to the work in wagons covered with canvas or other suitable material and upon reaching the street shall have a temperature between 93° and 163° C (200° and 325° F). The temperature of the binder mixture within these limits shall be regulated according to the temperature of the atmosphere and the working of the binder. On reaching the street it shall at once be dumped on the concrete and then be deposited roughly in place by means of hot shovels, after which it shall be uniformly spread by means of hot iron rakes and then at once thoroly compacted by tamping or rolling. Tamping shall only be permitted in those places which are inaccessible to a roller. Rolling shall be carried on continuously at the rate of not more than 300 sq yd per hr per roller until a compression is obtained which is satisfactory to the Engineer. The thickness of the finished binder shall average . . . in and not more than 40% variation from the average thickness specified will be permitted at any one spot. The upper surface of the finished binder shall be parallel to the established grade for the finished pavement. The surface after compression shall show at no place an excess of asphalt cement and any spot showing such excess shall be cut out and replaced with other material. All binder that shows lack of bond or that is in any way defective or which may become broken up before it is covered with wearing surface must be taken up and removed from the street and replaced by good material, properly made and laid in accordance with these specifications, at the expense of the Contractor. No more binder shall be laid at any one time than can be covered by a day's run of the paving plant on surface mixture. Binder when laid shall be followed and covered with wearing surface as soon as is practicable in order to effect the most thoro bond between the binder and the wearing course. The binder course shall be kept as clean and as free from traffic as is possible under working conditions. If necessary, it must be swept off immediately before laying the wearing surface on it. No binder shall be laid when in the opinion of the Engineer the weather conditions are unsuitable or unless the concrete on which it is to be laid is, even tho damp, free from pools of water and has set a sufficient length of time.

"13. Binder, Requirements. The finished binder must contain 4 to 7% of bitumen soluble in cold carbon disulphide, from 15 to 35% of material passing a 10-mesh sieve, and from 20 to 50% of material passing a ½-in screen, the percentage of bitumen to be regulated in accordance with the mesh composition and character of the mineral aggregate of the binder, and the percentage of material passing a 10-mesh sieve to be regulated in accordance with the traffic conditions upon the street or streets to be paved.

"14. Wearing Surface, Preparation. The wearing surface shall be composed of sand, filler and asphalt cement of the character elsewhere herein specified and mixed in proper and definite proportions by weight. The sand and the asphalt cement shall be heated separately to such a temperature as will give, after mixing, a surface mixture of the proper temperature for the materials employed. The sand when used must be at a temperature between 135° and 204° C (275° and 400° F). The asphalt cement when used must be at a temperature between 121° and 177° C (250° and 350° F). The various ingredients shall be brought together and mixed for at least 1 min in a suitable apparatus until a homogeneous mixture is produced in which all the particles are thoroly coated with asphalt cement. The weights of all materials

entering into the composition of the wearing surface shall be verified in the presence of inspectors as often as may be required and the Engineer or his representatives shall have access to all parts of the plant at any time.

"15. **Wearing Course, Laying.** The surface mixture prepared in the manner above described shall be brought to the work in wagons covered with canvas or other suitable material and upon reaching the street shall have a temperature between 110° and 177° C (230° and 350° F). The temperature of the surface mixture within these limits shall be regulated according to the temperature of the atmosphere and the working of the mixture and the character of the materials employed. On reaching the street it shall at once be dumped on a spot outside of the space on which it is to be spread. It shall then be deposited roughly in place by means of hot shovels, after which it shall be uniformly spread by means of hot iron rakes in such a manner that after having received its final compression by rolling, the finished pavement shall conform to the established grade. The thickness of the finished surface mixture shall average . . . in. Not more than a 10% variation from the average thickness specified will be permitted in any one spot. Before the surface mixture is placed, all contact surfaces of curbs, manholes, etc, must be well painted with hot asphalt cement. After raking, the surface mixture shall at once be compressed by rolling or tamping, after which a small amount of cement shall be swept over it and it shall then be thoroly compressed by a steam roller weighing not less than 200 lb to the in width of tread, the rolling being carried on continuously at the rate of not more than 200 sq yd per hr per roller, until a compression is obtained which is satisfactory to the Engineer. Such portions of the completed pavement as are defective in finish, compression or composition, or that do not comply in all respects with the requirements of these specifications, shall be taken up, removed and replaced with suitable material, properly made and laid in accordance with these specifications, at the expense of the Contractor. Whenever so ordered by the Engineer, a space of 12 in next to the curb shall be coated with hot asphalt cement, which shall be ironed into the pavement with hot smoothing irons. No wearing surface shall be laid when, in the opinion of the Engineer, the weather conditions are unsuitable or unless the binder on which it is to be placed is dry. Excessive use of water on the steam roller when compressing the pavement will not be permitted. The finished pavement must be well protected from all traffic by suitable barricades until it is in proper condition for use.

"Note. When the pavement is laid alongside of brick or concrete gutters, street car tracks, manhole heads, or liners, it is recommended that the finished surface adjacent to them be left ¼ in high, in order to provide for subsequent compression by traffic and to avoid depressions which would otherwise be liable to occur at these points.

"16. **Wearing Course, Requirements.** The finished pavement shall show, upon analysis, a mesh composition and bitumen contents within the following limits, sieves to be used in the order named:

Bitumen	9.5 to 13.5%		
Passing 200-mesh sieve. Not less than	10%	Total passing 200, 100 and 80-mesh......Not less than	25%
Passing 80-mesh sieve	10 to 35%		
Passing 50-mesh sieve	4 to 35%	Total passing 50 and 40-mesh	15 to 50%
Passing 40-mesh sieve	4 to 25%		
Passing 30-mesh sieve	4 to 20%	Total passing 30, 20 and 10-mesh	10 to 35%
Passing 20-mesh sieve	4 to 12%		
Passing 10-mesh sieve	2 to 8%		
Passing 8-mesh sieve	0 to 5%		

"The minimum amount of bitumen shall be used only in mixtures containing the minimum total passing the 80-mesh. The percentage of bitumen must be increased above the minimum as the total passing the 80-mesh increases. On streets of very light traffic, when the Engineer has approved the use of a coarser sand or mixture than that specified for general use, the surface mixture must contain not less than 6% of mineral matter passing a 200-mesh sieve and not less than a combined total of 18% passing the 200, 100 and 80-mesh sieves. The maximum amount of 200, 100 and 80-mesh material will be regulated according to the kind of sand and asphalt used

and the traffic upon the street on which the pavement is to be laid, subject to the maximum requirements elsewhere herein specified under sand and filler. The above limits as to mesh composition and percent of bitumen are intended to provide for such permissible variations as may be rendered necessary by the raw materials used and by the character of the work to be done. The composition of the wearing surface may be varied within the limits above specified at the discretion of the Engineer, depending upon the kind of sand, filler and asphalt used and the traffic conditions upon the street or streets to be paved."

Comments and Explanations of sections of the Am. Soc. Mun. Imp. 1916 specifications follow:

Sections 11, 12 and 13. The points in these sections have been fully discussed under BINDER and THEORY.

Sections 14, 15 and 16. The points covered in these sections have been fully discussed under METHODS OF MANUFACTURE AND LAYING, and THEORY. As in Sect. 7, the limits given include both light and heavy traffic mixtures and are wider than should be applied to any particular set of conditions. Under the provisions of Sect. 16 the engineer may and should narrow the limits to suit the conditions prevailing upon the streets to be paved and the available local material.

18. Construction Cost Data

Costs vary greatly, depending upon the price of materials and labor. In some localities sand and stone are very expensive and in others they are quite cheap. Freight rates on asphalt and other raw materials from their point of production to the place where they are to be used are a very important item. Where the climate is favorable and the work can proceed uninterruptedly, the labor costs are much lower than in rainy climates where frequent shut-downs are necessary and fuel and time are required to drive off excess moisture from raw materials and from foundations. Concrete and grading costs are generally so well understood that they will not be entered into here, as each engineer is familiar with them in his own particular locality.

Example of Cost Calculation. For the purpose of showing a typical cost calculation, it will be assumed that the pavement to be laid consists of a 1½-in binder course and a 1½-in wearing course, and that the binder is to contain 5% of bitumen, 25% of sand and 70% of stone, while the wearing course is to contain 11% of bitumen, 15% of filler and 74% of sand. The asphalt cement is to consist of 90% of refined asphalt and 10% of flux and will contain 96% of bitumen. The prices of the various raw materials delivered at the plant are:

Refined asphalt	$18.00 per ton gross, 5% tare,
Flux, 15° B gravity	0.07 per gal, no tare,
Binder stone	1.25 per cu yd, 2600 lb,
Binder sand	0.90 per cu yd, 2500 lb,
Surface sand, coarse	0.90 per cu yd, 2500 lb,
Surface sand, fine	1.00 per cu yd, 2500 lb,
Filler	5.00 per ton, net weight,
Coal	4.50 per ton.

ASPHALT CEMENT. Allowing for tare, 1900 lb of refined asphalt will cost $18. Flux of 15° B gravity weighs 8.05 lb per gal and hence would cost 0.87 cents per lb.

1900 lb refined asphalt @ $18.00	$18.00
211 lb flux @ 0.87 cents	1.84
2111 lb asphalt cement	$19.84 = 0.94

cents per lb for the asphalt cement.

Binder. As the asphalt cement is only 95% pure bitumen, the binder will contain 5.26% (5% ÷ 95%) in order to bring its bitumen contents up to the specified amount. This will cause a slight change in the percentages of stone and sand in the mixture.

1 cu yd binder stone (2600 lb) @ $1.25......	$1.25	69.81%
0.37 cu yd binder sand (928 lb) @ $0.90.....	0.33	24.93%
196 lb asphalt cement @ 0.94 cents..........	1.84	5.26%
	$3.42	100.00%

The sand and asphalt cement will increase the bulk of the stone but very little. Allowing for inequalities in the concrete, the above amount of binder mixture should lay 26 sq yd of binder course averaging 1½ in in thickness. The cost of materials for the binder course will therefore be 13.2 cents (3.42 ÷ 26) per sq yd.

Surface. As the asphalt cement is only 95% pure bitumen, the surface mixture must contain 11.58% (11% ÷ 95%) in order to bring its bitumen content up to the required amount. This will cause a slight change in the percentages of sand and filler in the mixture. The sand is to be mixed in the proportion of three parts of coarse to one part of fine and will therefore cost when mixed $0.925 per cu yd. Filler at $5 per ton will cost 0.25 cents per lb.

1 cu yd sand...	2500 lb @ 92½ cents per cu yd..	$0.925	73.52%
Filler.........	507 lb @ 0.25 cents per lb.....	1.27	14.90%
Asphalt cement	393 lb @ 0.94 cents per lb.....	3.69	11.58%
Surface mixture, 3400 lb	....	$5.885	100.00%

A standard wearing course 1½ in thick after being compressed, will weigh 150 lb per sq yd. 3400 lb will therefore lay 22.7 sq yd, hence the cost of materials for the wearing course will be $0.259 ($5.885 ÷ 22.7) per sq yd.

Fuel. The average cost of fuel for the plant and street should not exceed 2 cents per sq yd at the figures given for coal. It varies somewhat with the type of plant used and the daily output, the larger plants being the more economical. At the plant it is used under the boilers and the sand driers and on the street in the fire wagon and roller.

Labor at Plant

One foreman..........................	$3.00 per day,
One engineer.........................	2.50 per day,
One drum fireman,....................	2.00 per day,
One mixer man........................	2.00 per day,
Eleven laborers, @ $1.75	19.25 per day,
One night watchman...................	1.50 per day,
	$30.25 per day.

The above force with a suitable plant ought to be able to turn out sufficient material for not less than 800 sq yd of finished pavement per day of 10 hr. This assumes the plant to have a daily capacity of 1200 sq yd of surface or 2400 sq yd of binder. Plants vary very greatly in their output and the number of men required to work them, some being much more economical of labor than others. On this basis the plant labor should not cost more than 3.78 cents (30.25 ÷ 800) per sq yd for the finished pavement. Overtime, delays due to bad weather, and other causes usually run this figure up to from 4 to 5 cents per sq yd of finished pavement.

LABOR AT STREET

One foreman	$3.00 per day,
Three rakers @ $2.50	7.50 per day,
Two tampers @ $2.50	5.00 per day,
One roller engineer	4.00 per day,
Three shovellers @ $1.75	5.25 per day,
One cement sweeper	1.25 per day,
One fire wagon man	1.75 per day,
One laborer	1.50 per day,
One night watchman	1.50 per day,
	$30.75 per day.

The above force should easily handle and lay 800 sq yd of finished work per day of the thickness specified. On this basis the street labor would cost 3.84 cents ($30.75 ÷ 800) per sq yd of finished pavement, but, owing to delays, etc, this will usually run from 4.5 to 5.5 cents.

HAUL. Assume the average haul to be 2 miles and that each wagon will hold 5000 lb of mixture and that wagons and teams cost $5 per day. With this length of haul a wagon should average five round trips per day of 10 hr, during which it would carry 25 000 lb of material at a cost of $5,

25 000 lb of binder would lay	179 sq yd 1½ in thick,
25 000 lb of surface would lay	166 sq yd 1½ in thick.

The cost of haul per sq yd would therefore be:

Binder	2.8 cents ($5 ÷ 179)
Surface	3.0 cents ($5 ÷ 166)
Total	5.8 cents

ADMINISTRATION. When work of any magnitude is being carried on a general superintendent and a bookkeeper are required together with an office. The expense of this in a town where a plant of the size assumed would work economically would be approximately as follows:

General superintendent	$6.00 per day,
Bookkeeper	2.00 per day,
Office rent	1.00 per day,
Sundries	1.00 per day,
	$10.00 per day.

This would amount to 1.25 cents per sq yd ($10 ÷ 800) which should be increased to 2 cents to allow for delays.

GENERAL EXPENSE. Under this item would come expense of securing contract, promotion expense, head office expense, etc. This is such an uncertain quantity that it is hard to figure, but for ordinary conditions 5 cents per sq yd should cover it.

GUARANTEE BONDS AND MAINTENANCE FOR 5 YEARS. This again varies greatly with traffic conditions, etc, but will probably average 10 cents per sq yd for the entire period.

INTEREST ON INVESTMENT. Plant and street tools for the output under discussion would probably cost not less than $15 000. The interest on this at 6% would amount to $900 per annum. Assuming 180 full working days in a year, this would amount to $5 per day or ⅝ cents per sq yd. These conditions, again, vary so greatly as to make it impossible to estimate them accurately, but on the average 1 cent per sq yd should be a

fair charge. Larger plants with increased output would cost much more than $15 000, but the larger yardage of pavement laid with them would offset this. In many localities the conditions will permit of more than 180 full working days per annum.

REPAIRS AND DEPRECIATION. Ten per cent depreciation per annum and a yearly allowance of $900 for repairs would be reasonable for the conditions assumed in making this estimate. This would make a total of $2400, or $13.33 per working day for 180 days, which is equivalent to a cost of 1.66 cents per sq yd, say, 2 cents, per sq yd.

The total cost, exclusive of profit, for the pavement and conditions assumed is therefore:

Binder, materials	13.20 cents per sq yd,
Surface materials	25.90 cents per sq yd,
Fuel	2.00 cents per sq yd,
Labor at plant	4.50 cents per sq yd,
Labor at street,	5.00 cents per sq yd,
Haul	5.80 cents per sq yd,
Administration	2.00 cents per sq yd,
General expense	5.00 cents per sq yd,
Guarantee and maintenance for 5 years	10.00 cents per sq yd,
Interest on investment	1.00 cents per sq yd,
Repairs and depreciation	2.00 cents per sq yd,
Total cost per sq yd	76.40 cents per sq yd.

Character and Cost of Sheet-Asphalt Pavements in 1915 in Several Cities

From *Engineering and Contracting*, April 5, 1916

City	Square Yards	*Price per Square Yard	Guarantee Years	Wear'g Course Thickness, Inches	Binder Course Thickness, Inches	Concrete Foundation

* Price covers pavement, foundation, and preparation of subgrade.
† Does not include preparation of subgrade.

The general scheme of this cost calculation has been purposely made somewhat elaborate to show how all the various elements of cost may be figured. Where some of these elements are not involved they may be readily eliminated from the general scheme. Variations in the price of labor and materials will not involve any variation in the form of the calculation. It should be borne in mind that under certain conditions of large ouput, short haul and low maintenance cost, these figures may be considerably reduced. Where the price of materials is higher the cost will be correspondingly increased. The cost shown in the above calculation only covers binder and surface. Grading, foundation, curbing, manholes, and extra work are not included in it.

General Cost Data. Owing to the variation in the price of raw materials and the traffic conditions, it is impossible to give an average cost for standard sheet-asphalt paving construction which can be considered as authoritative or of great value. Exclusive of curbing and extra work, the average cost thruout the United States for a sheet-asphalt pavement, consisting of 6 in of concrete, 1½ in of binder and 1½ in of wearing surface, is probably about $1.80 per sq yd including grading to an average depth of not over 4 in. As illustrating the different conditions affecting prices, the foregoing table is given.

MAINTENANCE

19. Causes of Failure

The proper maintenance of a sheet-asphalt pavement involves the making of such repairs to it from time to time as are necessary in order that it may continue to render efficient service as a safe and smooth roadway or street.

The deterioration which eventually renders these repairs necessary commences as soon as the pavement is laid and may be broadly classified under the following heads: (1) Defects due to the wear and tear of traffic; (2) defects caused by the deterioration, thru age and exposure of the bituminous cementing material used; (3) defects in construction.

Traffic Deterioration. Under traffic the surface of the pavement is abraded and gradually wears off and the mineral particles exposed on the top are more or less crushed and broken. Where these particles are large, this crushing action is plainly noticeable, but with the smaller particles of sand it is hard to detect it. Under heavy traffic and unfavorable weather conditions, these crushed grains become active centers of disintegration. The crushed particles are not bound together by the asphalt cement and are soon swept away. The holes thus made in the pavement serve to retain the moisture and the edges of the holes are eventually more or less broken down, thus enlarging the hole. This condition reproduced all over the surface tends to make it wear away much more rapidly than would otherwise be the case. The effect of this action, which at first glance appears trivial, has been so well established by years of investigation and experience that it has become axiomatic in the paving industry that the heavier the traffic the finer must be the particles composing the mineral aggregate. In hot weather, when the pavement is plastic, the abrasion of the surface is much less than in cold weather, when the pavement is hard and possesses but little plasticity. In hot weather the calks on horses' shoes sometimes mark up the pavement to a very considerable extent, but the subsequent action of vehicular traffic wears these marks out almost completely. Nevertheless, in a community unaccustomed to sheet asphalt-

pavements, the appearance of these calk marks in a new pavement is always regarded as an ominous sign presaging its speedy destruction and failure. As a matter of fact, if the pavement, especially when newly laid, were not soft enough to show these marks it would be an almost infallible sign that the asphalt cement used in it was too hard and that the total life of the pavement would be less than if a softer asphalt cement had been used. Traffic on a pavement always compresses it and increases its density, and for this reason a two-year-old pavement will always mark up less than a new one. The pressure per square inch exerted by the comparatively narrow tire of a heavily loaded vehicle is much greater than that exerted by the heaviest steam roller used in the laying of sheet-asphalt pavements. Even if this were not the case, the kneading action produced by narrow tires passing many times over the surface would always give greater compression than could be obtained by the action of the broad tires of a steam roller.

When the traffic is confined to a comparatively narrow space and is always in the same direction, a distinct pushing force is exerted on the pavement. Whenever the pavement lacks inherent stability, due to an improper mineral aggregate or bitumen which is lacking in cementing value from natural causes or the rotting action of gas or water, or a combination of these defects, very distinct waves or bumps will be produced by the action of heavy traffic. These waves sometimes occur in recently laid pavements in which the asphalt cement used was of the highest quality, but in such cases will usually be confined to a few places. Investigation will almost always show defective binder in these spots, or too soft an asphalt cement, or too great a thickness of pavement owing to an error in the grade of the concrete. A paving mixture, designed to have proper stability when laid 2 in thick, will often fail in this respect when laid 4 in thick, which is the explanation in the case last cited. Too soft an asphalt cement will also reduce the stability of a pavement. Once these waves appear, they are aggravated by traffic passing over them. The wheel of each vehicle rises to the crest of the wave and then drops down with considerable force into the adjacent depression. The plastic pavement in this way is continually displaced at the low spots and shoved up at the high spots until in many instances the concrete will be exposed at the bottom of the depression. Similar depressions are produced by setting manholes too high above the surrounding pavement. Vehicles drop off these high manhole covers onto the pavement and soon pound it out of place. It is better to set all manholes slightly below the grade established for the finished pavement.

Waves are much less liable to appear in those portions of the pavement which are subjected to cross traffic; that is, in which the traffic does not always move in the same direction. This is usually the case at street intersections, and, if properly constructed, the pavement in these locations almost always lasts longer than in any other part of the street. It has been seriously suggested that in order to increase the effective life of pavements, the direction of the traffic in the afternoon should be the reverse of that in the morning, but the resulting confusion would probably more than offset the gain from such a procedure. Car tracks in a street paved with sheet-asphalt may cause the pavement to deteriorate very rapidly. Unless the rails are very heavy and laid on an adequate foundation, they will vibrate excessively when cars pass over them. This is especially the case where tracks designed for light city or town cars are subsequently

called upon to carry heavier cars or cars of the interurban type. Not only will the vibration be excessive, but the rails will frequently sink below the level of the pavement and leave depressions where the water will collect. To prevent the vibration from being communicated directly to the sheet-asphalt, rows of paving blocks or bricks are frequently placed along the rails, altho in many cases the sheet-asphalt is brought up directly to the rails. When the vibration is excessive, the sheet-asphalt pavement crumbles or cracks in a very short time and leaves an opening for surface water to enter between the wearing surface and the concrete foundation, thus permitting the rotting action elsewhere described to take place.

Effect of Ageing and Exposure. All bituminous materials used in paving work deteriorate upon exposure to the elements and to the rotting action of escaping gas, water and street liquids. The lighter oils contained in them gradually volatilize, thus hardening the remaining bitumen. As the hardening process goes on, the pavement loses its plasticity and wears away with increased rapidity. Eventually the bitumen loses its elasticity and the pavement cracks. The edges of these cracks crumble away and the cracks become sufficiently wide to be plainly felt by vehicles passing over them. The bumping action previously described in connection with waviness is produced and adds to the rapidity with which crumbling takes place. In order to guard against this and prolong the effective life of the pavement, the asphalt cement used in its construction is made as soft as possible without rendering the pavement too mushy when new. The extent to which this can be carried depends upon the grading and character of the sand employed. With a well graded sharp sand and plenty of filler, a much softer asphalt cement can be used than with a poorly graded or rounded sand. This is due to the greater inherent stability of the former type of sand. It is obvious that a mineral aggregate which when dry strongly resists displacement will permit the use of a comparatively soft asphalt cement. Modern traffic conditions have in this particular respect come to the aid of the pavement makers. Automobiles in their passage over the pavement are continually dropping a certain amount of oil on its surface which is very evenly distributed by the large number of vehicles passing over it. This oil is gradually absorbed by the pavement and thus softens the bitumen and counteracts to a large extent the hardening action of time upon it. This is very clearly shown in a certain pavement in Chicago, which, prior to the passage of any considerable number of automobiles over it, about 1910, was so hard and badly cracked as to have practically reached its limit of usefulness. The street in question subsequently developed into an automobile center with the result that the pavement was softened up by the dropping of oil upon it to such an extent that, in 1915, it was still giving satisfactory service. Fifth Ave., New York City, is a somewhat similar case.

Some asphalts are more easily rotted by water action than are others. With such asphalts it is more than ever necessary to make the pavement as dense as possible to prevent the water from getting into it. Generally speaking, with all asphalts the wetter the climatic or other conditions, the denser and richer in bitumen should the mixture be made. The action of water upon a pavement may take place from the surface downward or from the bottom upward. The latter action is the more serious and the harder to guard against. The top surface is always compressed to its maximum density by the action of traffic, and if it has sufficient crown and grade to let the water run off and is kept clean so that

it will not be covered by a layer of wet mud for long periods, but little deterioration will take place. Where water is allowed to remain in the gutters, the rotting will frequently be very rapid and this will be still more marked if, as in some towns, the dirty wash water from houses is discharged into the gutters. Too frequent washing of a pavement with water at a high pressure is also bad, as the abrasive action of such a jet is very considerable and acts in the same way as the stream from a hydraulic nozzle. In a number of cases water finds its way between the wearing surface of the pavement and the concrete foundation. This may be due to the geological formation of the subsoil strata (and it must be remembered that concrete is not waterproof, especially the type used for foundation work) or the water works its way down between car tracks and the abutting pavement, or thru faulty gutter construction, etc. Under such conditions, it has little or no chance to evaporate or drain off and attacks the pavement at its weakest point, that is, where the compression is the least. It gradually destroys the life of the bitumen and renders it incapable of cementing the grains of sand together. This action progresses upward thru the pavement and in some cases is not apparent until only a top shell of good pavement remains. Depending upon the conditions, this action usually manifests itself by shoving and waviness of the pavement at the point where the rotting has taken place. Owing to the loss of the cementing power of the bitumen, the stability of the pavement has been lowered so that it can no longer withstand the shoving action of traffic previously described. If the pavement is cut thru at this point, the white sand grains will be plainly apparent and the whole mass can be readily disintegrated between the fingers. As soon as the rotting action reaches the surface, the pavement is quickly worn away by traffic and a hole is produced.

Gas leaks produce a very similar result and the gas sometimes travels a long distance from the point of leakage before it actually comes in contact with the pavement.

Another cause for the deterioration of sheet-asphalt pavement is lack of traffic. Pavements laid on outlying residence streets and culs-de-sac with little or no traffic, crack much more quickly than if they were subjected to a moderate traffic, which appears to be necessary to keep the life in the pavement. This is probably due to the fact that the surface is not in such cases kept at the maximum density by the action of traffic and gradually becomes porous, thus facilitating the evaporation of the lighter oils and also to the fact that the kneading action of traffic, like the continual use of a rubber band, tends to keep the life, so to speak, in the bitumen and equalizes the stresses set up by contraction and expansion.

Defects in Construction. These may perhaps be more clearly understood by a general discussion of the principles involved and the correct way of carrying them out and coincidentally calling attention to the particular defects arising from marked departures from standard practice.

Unless the foundation is rigid and of sufficient strength to carry the weight of the traffic passing over the finished pavement, no sheet-asphalt wearing surface will give satisfactory service. Being plastic at all normal temperatures, the wearing surface will not bridge over any depressions formed by the sinking or failure of the foundation, but will sink with it. The principles governing good foundation work and design need not be considered here except to say that the subgrade must be well rolled and compacted in the first place and that good concrete of sufficient strength and thickness should then be put in place and allowed to set before any

binder or wearing surface is put upon it. Assuming that the subgrade has been properly rolled and that the concrete is of the proper thickness and quality, the first point of importance is to see that it is laid to grade. If it is too high in places, the thickness of the binder and wearing surface must be reduced in order that the surface of the finished pavement may conform to the established grade. Any marked diminution in the thickness of the wearing surface will, under heavy traffic, considerably reduce the life of the pavement. On the other hand, if the concrete is laid too low, the thickness of the binder and wearing surface will have to be increased. Within limits, this is not objectionable if the increased thickness is not carried to such an extent as to affect the stability of the pavement, otherwise it will tend to roll and push out of shape under traffic, as previously described. It is usually considered better practice to leave the surface of the finished concrete somewhat rough in order that the binder may key into these depressions and still further resist the shoving action of traffic. After the concrete has been put in place, ample time should be allowed for setting, and this will vary with the weather conditions. Concrete laid in freezing weather will apparently set up when in reality it has frozen. When the hot binder and surface mixture are placed on frozen concrete, the latter is thawed by the action of the heat and becomes mushy and has not sufficient strength to support the weight of the steam roller. Under such circumstances it is impossible to properly compress the hot mixture. In addition to this, the water set free by the thawing of the concrete is forced into the mass of hot material and more or less of it remains entrained in the mass.

In most forms of construction, a binder is laid directly on top of the concrete, altho this is sometimes omitted and a paint consisting of asphalt dissolved in naphtha is applied directly to the dry surface of the concrete and the wearing mixture laid directly on this.

A close binder properly made and laid will be superior in many respects to the mixtures which have been laid on a large number of country highways and will carry a fair amount of traffic for a considerable time without suffering any serious damage. Poor binder will break up very easily, sometimes it can be kicked up, and the hauling of the hot surface mixture over it will damage it very seriously. Surface mixture laid on a binder of this kind which has been badly broken up might almost as well be laid on loose broken stone and will not give satisfactory service under heavy traffic.

Lack of compression will produce an unsatisfactory foundation for the wearing surface, and, as previously mentioned, binder which is too cold or made with too hard an asphalt cement or an insufficient quantity of asphalt cement can not be properly compressed into a dense, tough mass. In hauling the binder to the street over long distances or in very cold weather, it may become chilled below the danger point.

Before laying the surface mixture on the finished binder course, the latter should be dry and swept clean of dirt; otherwise the layer of wearing surface will not adhere properly to it. When delivered upon the street, the mixture should be of such a temperature that it can be properly compressed and should be evenly spread by means of hot iron rakes. In many cases the loads of hot surface mixture are dumped directly upon the spot over which they are to be spread. This is bad practice, as the men trample upon it while shovelling and raking it and the rakes do not thoroly loosen up this trampled material when passing over and thru it. Altho the mixture is raked to a uniform surface and apparently even thickness before it

is rolled, those portions which have been trampled on before and during raking are really covered with a greater quantity of surface mixture than those portions which have not been trampled on and which are covered wholly with what might be termed loose or fluffy mixture. When the roller has completed its work there will, therefore, be a slight unevenness in the finished surface. Under light traffic this would make no appreciable difference, but under very heavy traffic the slight pounding action resulting from this condition would be detrimental and lead to uneven wear of the pavement. Proper and thoro compression of the finished mixture is very essential as this produces a pavement which in its earliest stages is fit to sustain the heaviest traffic. It is always questionable whether portions which are very lacking in compression will be ground out or eventually consolidated. Under unfavorable conditions the chances are strongly in favor of their being ground out. In those portions of the pavement which are inaccessible to the roller, compression is affected by the use of hot smoothers or tampers, or both. If properly handled, the desired results will be obtained, but if used too hot, they will burn the pavement and cause it to scale or grind out. Hot smoothers particularly are dangerous tools to put in the hands of incompetent or careless workmen.

The practice of painting the edge of the joint with hot asphalt cement is not to be recommended, as, unless extreme care is exercised, too much asphalt cement will be used and that portion of the pavement will be too rich in bitumen and consequently softer than the rest, which will result in uneven wear and possibly shoving. Great care should be taken not to have any hump or depression when the joint is made.

A Summary of the Chief Defects and Failures met with in practice and the contributing causes is given below.

Cracking is due to cracking of the concrete base; hardening of the asphalt cement thru age; use of too hard an asphalt cement; use of an unsuitable asphalt cement; too little bitumen in the surface mixture; insufficient compression; lack of traffic; improperly constructed joints; extreme and sudden changes in temperature; vibration of street-car rails.

Disintegration of Surface is due to defective base; unsuitable mineral aggregate; insufficient bitumen in mixture; insufficient compression; use of too hard an asphalt cement; use of overheated mixture; burning due to use of excessively hot smoothers; action of water; action of illuminating gas.

Waviness is due to use of an unsuitable sand; use of too soft an asphalt cement; unstable binder; lack of stability in mixture; too great a thickness of mixture; projecting manholes; action of water; action of illuminating gas; uneven raking; too much bitumen in mixture; excessively heavy traffic in one direction over a limited area.

Scaling is due to too coarse a mineral aggregate; too hard an asphalt cement; action of water; accumulation of mud; too little bitumen; excessively heavy traffic.

20. Methods of Repairing

Repairing should be carried on within a reasonable time after defects first make their appearance. If this is neglected, deterioration proceeds much more rapidly than would otherwise be the case. Holes and depressions are increased in size by the passage of vehicles over them and water accumulates in them, accelerating disintegration.

Two distinct methods of repairing are in general use: (1) The pavement is cut out and removed down to the concrete and replaced with new binder

and surface; (2) the upper portion of the surface is first heated by suitable appliances and a thin layer of it removed by rakes and shovels. Immediately thereafter and while the remaining pavement is still warm, a comparatively thin layer of new hot surface mixture is spread over it and raked and compressed in the usual manner followed in the construction of new pavements.

Pavement Cut Out and Replaced. The first method is so simple that but little description of it would appear to be necessary. The defective pavement is cut up into pieces sufficiently small to facilitate its removal and pried up with crowbars if necessary. The adjacent edges of the old pavement are trimmed up with an asphalt cutter and sparingly painted with hot asphalt cement to insure a proper bond between the old and new portions. Under favorable conditions and when the pavement being repaired is not too old and hard, this painting with asphalt cement may well be omitted. All loose debris is removed down to the concrete and a new binder course and wearing surface is then laid in exactly the same manner as when constructing a new pavement. This method should always be employed in filling up holes and depressions or wherever the defective pavement is in such shape as to necessitate its complete removal, as in the case of rotting from the bottom upward and waviness, defective binder or foundation, etc.

Heating Surface of Pavement and Adding New Material. The second, or surface heater method of repair, is conducted as follows: The surface heater is placed over the defective pavement and put in operation. Superheated steam, hot air or flame is then brought in contact with the surface and is allowed to remain there until the pavement has been softened to the required depth, usually from $\frac{3}{4}$ to 1 in. The heater is then withdrawn and placed on the next spot to be repaired and the burned material completely removed. The space thus left is immediately filled with new hot surface mixture which is spread, raked and finished in the usual manner. Care must be taken to completely remove all burnt material down to such a depth that the new surface after compression will be not less than $\frac{3}{4}$ in in thickness. Skin patching of less depth than this has not proven satisfactory. In order that repairs made by this method will give satisfactory service, it is essential that the remainder of the old pavement which serves as a foundation should be sound and in good condition and free from water rotting. It is not applicable to the class of repairs rendered necessary by defective binder, or foundation, or water, or gas rotting. When it becomes necessary to resurface, wholly or in part, a pavement which has become too hard thru age to give satisfactory service, the surface heater method gives very good results and is much cheaper than a complete removal of the old pavement down to the concrete. By applying the hot new surface mixture to the remaining portion of the old pavement while the latter is still hot from the action of the heater, a satisfactory union between the old and new work can readily be obtained, provided that the hardening of the old pavement has not been allowed to proceed so far that it is impossible to soften it by the application of heat. Cracks may in most cases be more successfully repaired by this method than is possible in any other way. The repairing of cracks satisfactorily is a very difficult matter. If they are cut out and new material put in, this results in the formation of two joints approximately parallel to the original crack. If the pavement being repaired is old and hard, it is difficult to establish a good bond between the old and new portions, and unless this is accomplished, two

cracks will shortly appear where only one existed before. This is especially the case where long cracks make their appearance at considerable intervals and in many instances these had better be left until they become sufficiently wide or numerous to render more or less extensive resurfacing necessary at the places where they occur.

21. Guarantees

In the early days of the industry 15-year guarantees were common. This was subsequently cut to 10 years and finally to 5 years, which last is the most satisfactory. Under fairly heavy traffic, a 10 or 15-year guarantee involves so many uncertainties that in order to protect himself from financial loss a contractor must bid a high price. The character of the traffic may completely change in this period and the type of construction originally employed be absolutely inadequate to meet changed conditions. Long guarantees usually result in very high prices and severely handicap the smaller contractor. The large concern with a number of streets in different localities to maintain is able to apply the excess revenue from the maintenance of some of their streets to offset unexpectedly heavy drains on others. Bonding companies soon perceived the fallacy of acting as sureties on long term maintenance. The many considerations entering into the construction of a sheet-asphalt pavement are not well known to most city officials and they are therefore unable thoroly to supervise the laying of it. Without thoro and trained inspection they are at the mercy of the contractor, who himself is often more or less ignorant of the principles of the art. A guarantee for a moderate period, say 5 years, is therefore a useful protection provided the bonding company and the contractor live up to their obligations. Past experience conclusively shows that even this safeguard is often woefully lacking in real value and that the only proper method is to have competent supervision of the pavement while it is being manufactured and laid. Many of the larger cities have organized their own inspection departments and the smaller ones who can not afford this expense are employing inspecting engineers.

22. Specifications for Maintenance

The following specifications were adopted in 1916 by the Am. Soc. Mun. Imp. At the conclusion of the specifications, comments and explanations pertaining to several sections have been appended.

"17. **Condition at Expiration of Guarantee.** In addition to the proper maintenance of the pavement during the period of guarantee, the Contractor shall, at his own expense, just before the expiration of the guarantee period, make such repairs as may be necessary to produce a pavement which shall:

a. Have a contour substantially conforming to that of the pavement as first laid and free from depressions of any kind exceeding ½ in in depth as measured between any two points 3 ft apart on a line conforming substantially to the original contour of the street.

b. Be free from cracks or depressions showing disintegration of the surface mixture.

c. Contain no disintegrated surface mixture.

d. Not have been reduced in thickness more than ⅜ in in any part.

e. Have a foundation free from such cracks or defects as will cause disintegration or settling of the pavement or impair its usefulness as a roadway.

"18. **Repairing.** Repairs, except as provided for below, shall in all cases be made by cutting out the defective binder and wearing surface down to the concrete and replacing them by new and freshly prepared binder and wearing surface made and laid in strict accordance with these specifications. Whenever any defects are caused by the failure of the foundation, the pavement, including such foundation, shall be taken

up and relaid with freshly prepared material made and laid in strict accordance with these specifications. In all cases the surface of the finished repair shall be at the grade of the adjoining pavement and in accordance with the contour of the street.

"The surface heater method of repairing may be used only in those cases where the repairs are not rendered necessary by: (1) Failure of concrete; (2) failure of the binder; (3) failure caused by the disintegration of the lower portion of the wearing surface. Whenever the surface heater method is employed, all defective surface shall be removed before replacing it with new material. In all cases the old surface shall be removed to a depth of not less than ¼ in and the new surface must, when compressed, be not less than ½ in in thickness. The heat shall be applied in such a manner as not to injure the remaining pavement. All burnt and loose material shall at once be completely removed and, while the remaining portion of the old pavement is still warm, shall be replaced by new and freshly prepared wearing surface made and laid in strict accordance with these specifications.

"19. NOTE TO ENGINEERS. Filler. As Portland cement is more expensive than limestone dust, the specification should distinctly state which kind of filler is desired.

"Binder. The following clause has been suggested as being descriptive of the practice in some cities. The committee, however, does not feel like recommending it in a general specification. If this clause is incorporated in the specifications it should be clearly stated whether or not the practice described therein will be permitted by the City Engineer.

"With the permission of the City Engineer, not to exceed 20% of crushed old asphalt surface mixture of suitable character may be used in combination with the binder stone, provided that such mixture produces a binder complying in all respects with the requirements of these specifications."

Comments and Explanations of sections of the Am. Soc. Mun. Imp. 1916 specifications follow:

Section 17. This is intended to insure that the pavement at the expiration of the guarantee period shall be handed over to the city in a serviceable condition. It is not intended to place upon the contractor the burden of repairing defects other than those caused by defective workmanship or materials or ordinary wear and tear.

Section 18. This specifies the manner in which repairs shall be made and these are discussed at length under METHODS OF REPAIRING.

Section 19. This suggests a clause permitting the use of crushed old surface mixture in the binder mixture instead of sand. The cold crushed material should be added to the hot stone after it has passed thru the heating drums and then be mixed with it until both materials have reached approximately the same temperature. If the surface mixture were passed thru the ordinary drying drums with the sand it would be burnt and become unfit for use. If desired, drums or heating devices of special construction to avoid overheating may be used for heating the surface mixture. Only a surface mixture of suitable character shall be used.

ROCK ASPHALT PAVEMENTS

GENERAL DATA

23. Description and Historical Development

General Description. Rock asphalt pavements differ from sheet-asphalt pavements in that the mineral aggregate has been impregnated by nature with a bituminous cementing material. The mineral aggregate consists of sand or finely divided limestone and will generally all pass a 10-mesh sieve. They are usually laid directly on a concrete foundation, the binder course used with sheet-asphalt pavements being generally omitted.

History. European rock asphalt pavements have a mineral aggregate composed of finely divided limestone impregnated with a very soft bitumen. Commercial deposits of this material occur in France, Italy and Germany and have been known since 1712. The Val de Travers deposits in Switzerland have been worked since about 1720, those at Lobsann, Germany,

since about 1735, and those at Seyssel, France, since about 1797. Count de Sassenay in 1802 greatly improved the old and very crude method of mining and handling the material. At first only an asphalt mastic was manufactured and this was produced by enriching the ground rock with additional bitumen extracted from rock obtained from the same deposit. The rock asphalt mastic so produced was used for paving floors, sidewalks and, finally, streets. In 1834 mastic pavements met with some success in Lyons, France. About the same date mastic began to be used extensively in Paris for sidewalks. It was not until 1854 that the compressed rock, but not in the form of mastic, was used in street pavements and in that year Leon Malo paved the Rue Bergere in Paris with it. This proved successful and its use spread rapidly. In 1869 Threadneedle St., in London, was paved with Val de Travers rock asphalt and in 1871 rock asphalt pavements were laid in Geneva and Berlin. Shortly thereafter similar pavements were laid in New York City, Boston, Buffalo, New Orleans, La., and other American cities, but the high cost of importing the rock asphalt from Europe and the invention of the American type of sheet-asphalt pavements, which could be laid at a much lower cost, eventually led to its practical abandonment in the United States as a street pavement. Large quantities of mastic for flooring, waterproofing and sidewalk work are, however, still imported. Numerous bituminized sand and limestone rock deposits are found in the United States altho the former predominate. It is probable that the bituminized sands at Carpinteria, near Santa Barbara, Cal., were the first ones used for paving roadways in the United States and that they were employed about 1865. Bituminous limestone deposits are found in the United States in Oklahoma, Texas and Utah, and bituminous sandstones are found in Kentucky, Oklahoma, California, Texas and Utah. Many of them have been utilized for paving purposes but generally only in the immediate neighborhood of the deposits, as, except within a limited distance, they could not compete in price with a sheet-asphalt pavement.

24. Characteristics

Rock asphalt pavements, when properly constructed, closely resemble sheet-asphalt pavements in many respects. They are smooth, non-productive of dust, almost noiseless, waterproof, non-absorbent and easy to clean. Limestone rock pavements are smoother and more slippery than sheet-asphalt pavements. They do not soften up to the same extent in hot weather and the best type will probably sustain a slightly heavier traffic. Some of the heaviest traffic streets in cities in Europe are paved with them. Sandstone rock pavements when containing a properly graded mineral aggregate are practically identical in appearance and texture to sheet-asphalt pavements. Most natural deposits are impregnated with a soft bitumen and their mineral aggregate is not well graded. Under such conditions they mark up excessively in hot weather and are very liable to displacement under traffic and their use has been chiefly confined to light traffic streets.

Foundations should be the same as for sheet-asphalt pavements.

MATERIALS

25. Bituminous Limestones and Sandstones

Bituminous Limestones. Those obtained from Europe are more evenly impregnated with bitumen than are those found in the United States and

compact better and much more readily. It has been suggested that the Continental limestone matrix consists of the remains of marine organisms, which may account for this. Most of the American limestone rock contains particles of hard crystalline calcite which has not been impregnated with bitumen. The mesh composition of the European rock asphalts given in the following table represents the material as it reaches the United States after pulverization.

Table II.—European Bituminous Limestones

	1	2	3	4	5	6
Bitumen	6.1%	8.7%	8.5%	10.0%	9.8%	7.5%
Passing 200-mesh	42.9%	47.3%	37.5%	40.0%	35.2%	17.5%
Passing 100-mesh	9.0%	10.0%	15.0%	12.0%	17.0%	25.0%
Passing 80-mesh	6.0%	6.0%	12.0%	8.0%	11.0%	20.0%
Passing 50-mesh	7.0%	9.0%	14.0%	10.0%	14.0%	15.0%
Passing 40-mesh	8.0%	5.0%	4.0%	7.0%	9.0%	8.0%
Passing 30-mesh	8.0%	5.0%	4.0%	6.0%	2.0%	3.0%
Passing 20-mesh	7.0%	5.0%	3.0%	4.0%	1.0%	2.0%
Passing 10-mesh	6.0%	4.0%	2.0%	3.0%	1.0%	2.0%
	100.0%	100.0%	100.0%	100.0%	100.0%	100.0%
Carbonate of lime	91.3%	87.1%	88.4%	88.2%	75.2%	80.0%
Carbonate of magnesia	Trace	0.9%	Trace	0.9%	13.5%	0.5%
Consistency of impregnating bitumen	Very soft	Very soft	Very soft	Very soft	Very soft	Very soft

(1) Seyssel, France; (2) Mons, France; (3) Val de Travers, Switzerland. (4) Ragusa, Sicily; (5) Sicula, Sicily; (6) Vor Wohle, Germany.

The bitumen contents of these rocks varies considerably in different portions of the deposits and the above figures represent the average as shipped to this country. Until the necessity was realized for blending materials from different parts of the deposit so as to produce a uniform product, many failures resulted.

Table III.—American Bituminous Limestones

	1	2	3	4	5
Bitumen	4.6 to 12.0%	3.0 to 7.0%	3.5 to 10.5%	10.0 to 13.0%	5.0 to 13.0%
Carbonate of lime and magnesia	78.0%	87.0%	72.0%	87.5%	63.0%
Penetration at 25° C (77° F) of impregnating bitumen	20 to 55	30 to 60	200 to 225	15 to 25	5 to 20

(1) Buckhorn, Okla.; (2) Brunswick, Okla.; (3) Ravia, Okla.; (4) Uvalde County, Tex.; (5) Clear Creek, Utah.

Bituminous Sandstones. In most of these deposits the material is very imperfectly impregnated and the rock does not break down after the extraction of the bitumen from it. In some of them the bitumen is too hard and requires fluxing; in others, it is too soft or present in too great quan-

tities and bituminous sandstones have been mixed with them with good results, notably in the case of the Buckhorn bituminous sandstones and limestones, mixtures of which have been laid in Kansas City, Mo. Some excellent pavements have been laid in Beaumont and San Antonio, Texas, by mixing the pulverized Uvalde County bituminous limestone with flux to soften the hard bitumen or with flux and sand.

Table IV.—American Bituminous Sandstones

	1	2	3	4	5	6	7
Bitumen	18.5%	10.8%	17.5%	6.5%	7.5%	11.5%	10.5%

Penetration at 25° C (77° F) of impregnating bitumen	Very soft	Very soft	Very soft	Very soft	Very soft	Very soft	Very soft

(1) Carpinteria, Santa Barbara County, Cal.; (2) Santa Cruz, Cal.; (3) Santa Cruz, Cal.; (4) Breckenridge County, Ky.; (5) Green River, Warren County, Ky.; (6) Buckhorn, Okla.; (7) Whitmore Canon, Utah.

The Carpinteria sands are too rich in bitumen to make a satisfactory pavement altho they have been used to some extent in and around Santa Barbara. The Santa Cruz material if carefully selected makes a very satisfactory light traffic pavement and a large amount of it has been laid in San Francisco. Where failures resulted, it was chiefly due to lack of care in selecting the material. Certain of the Kentucky rock asphalts have been used in Louisville, some of the pavements being very poor, due to ignorance and poor selection of material, and others being very good. A number of excellent pavements were laid in the above City by mixing a certain proportion of the heated bituminous sandstone with an ordinary sheet-asphalt mixture. Where the rock has been uniformly impregnated with bitumen, the coating of the particles is usually much more thoro than is possible in an artificial mixture. This is especially true where the mineral aggregate is composed almost wholly of very fine particles, as in the case of certain of the European limestone rock deposits. The difficulty of obtaining uniform material in which the consistency of the bitumen and the grading of the mineral aggregate are satisfactory is, however, very great. In a sheet-asphalt pavement this is easily regulated. The sand which constitutes 70 to 80% of it is derived locally, and this is often true of the filler as well. While the freight rate on the asphalt used may be high, it only constitutes approximately 10% of the pavement. Where a natural bituminous rock is used, the entire pavement must be transported and when the distances are great this is a prohibitive handicap. For these reasons the rock asphalt industry of the United States has never assumed large proportions and most of the pavements have been laid in the immediate vicinity of the deposits. Some cities, notably Buffalo, have used a certain proportion of European rock in their sheet-asphalt paving mix-

tures with success. If finely ground, it takes the place of the filler and is already thoroly impregnated with bitumen.

26. Theory and Composition of Rock Asphalt Pavements

The Theory governing bituminous sandstone mixtures is substantially the same as for sheet-asphalt mixtures. In the case of bituminous limestone pavements made from European rock asphalts, the mineral aggregate is largely composed of 200, 100 and 80-mesh particles, which of themselves pack dry and possess great stability. These particles are impregnated with a very soft bitumen. Considering the surface area of the particles, the amount of the bitumen is relatively much smaller than that used in sheet-asphalt pavements. For the above reasons the wearing course of European limestone rock asphalt pavements is possessed of great stability and very rarely shoves under traffic. This is not true of the bituminous sandstone pavements, most of which, unless impregnated with a very hard bitumen, are lacking in stability.

Table V.—Composition of Rock Asphalt Pavements

	1	2	3	4	5	6
Bitumen	9.0%	8.5%	12.9%	13.4%	15.8%	9.7%
Passing 200-mesh	35.0%	16.5%	19.1%	14.6%	18.2%	12.3%
Passing 100-mesh	16.0%	8.0%	8.0%	4.0%	22.0%	22.0%
Passing 80-mesh	15.0%	19.0%	8.0%	5.0%	15.0%	24.0%
Passing 50-mesh	14.0%	14.0%	19.0%	13.0%	10.0%	28.0%
Passing 40-mesh	8.0%	9.0%	6.0%	7.0%	11.0%	2.0%
Passing 30-mesh	2.0%	12.0%	13.0%	9.0%	3.0%	1.0%
Passing 20-mesh	1.0%	8.0%	10.0%	9.0%	3.0%	1.0%
Passing 10-mesh	....	5.0%	4.0%	10.0%	2.0%	....
Retained 10-mesh	....	....	....	15.0%	....	....

(1) Plaza, 5th Ave. and 59th St., New York City, European limestone rock asphalt; (2) Kansas City, Mo., mixture of Oklahoma bituminous sand and limestone; (3) San Antonio, Tex., Uvalde County, bituminous limestone fluxed; (4) Beaumont, Tex., bituminous limestone fluxed; (5) San Francisco, Santa Cruz bituminous sandstone; (6) Louisville, Ky., mixture of Kentucky bituminous sandstone filler and asphalt cement.

CONSTRUCTION AND MAINTENANCE

27. Methods of Manufacture and Laying

Manufacture. If the mineral aggregate is naturally in a fine state of division and only held together as a solid mass by the cementing power of the bitumen which it contains, it will usually be unnecessary to pulverize it; otherwise, it must be passed thru rollers and disintegrators and then screened to separate any lumps which may remain. The American and European limestones require crushing, while most of the bituminous sandstones do not. After crushing they are then heated in revolving drums somewhat similar to the sand dryers used in sheet-asphalt plants but having a much smaller grate area as great care must be taken not to overheat or burn the material. Usually a definite charge is placed in the drums and subjected to a heat of not over 177° C (350° F). The drum is con-

tinuously revolved until the powdered rock reaches a uniform temperature of approximately 149° C (300° F). This usually requires about 2 hr. Continuous feeding, as in a sand drier, is not often practiced, as, to insure sufficient heating during the passage of the material thru the drum, there would be too great danger of burning it. This heating is sometimes done in shallow iron pans with a slow fire underneath, the powdered rock being continually turned over by hand during the process. Where asphalt cement or sand is to be added, the ordinary type of asphalt mixer, sand drier, etc, must be provided in addition to the equipment above described. If no such addition is required, the bituminous rock is ready to lay on the street as soon as it comes from the heating drum.

Laying. The hot powder is transported to the street in wagons and spread with hot iron rakes to a uniform depth in much the same manner as a sheet-asphalt pavement. Bituminous sand mixtures are usually rolled and finished in the ordinary way. Bituminous limestone pavements are sometimes, but not always, rolled with a light hand roller as soon as they are raked. Immediately thereafter they are tamped over their entire surface with round tampers from 6 to 7 in in diameter, after which they may or may not be rolled with a 5 to 10-ton steam roller. Joints are made in the customary manner and smoothers are sometimes used on them, but the freshly cut edges are not painted with asphalt cement. In a bituminous limestone pavement the compression effected as above described results in the production of a skin of compressed paving mixture on the surface. The lower portion of the wearing course receives much less compression than does a sheet-asphalt pavement similarly treated, as the powdered rock is light and fluffy and can only be compacted thruout with great difficulty and years of traffic are required to produce ultimate compression. This does not militate against the successful use of this material as a pavement, however. In fact, shortly after ultimate compression has been reached, the pavement commences to disintegrate. The street tools used differ but little from those employed in the sheet-asphalt paving industry.

28. Specifications for Construction

These vary greatly with the kind of material used and the method of manufacturing or tempering it. Owing to the limited use of rock asphalt pavements in the United States, these specifications are not as detailed or as nearly standardized as are sheet-asphalt paving specifications.

Borough of Manhattan, New York City, 1912 Specifications. "Should any of the rock asphalts be used, the material shall be a natural bituminous limestone or sandstone, or a mixture of the two, and shall be prepared and laid in the following manner:

"The lumps of rock, after being mixed in the proper proportions, shall be finely crushed and pulverized, and the powder passed thru a 20-mesh sieve. In case of the use of any asphaltic limestone, or a mixture of an asphaltic limestone and an asphaltic sandstone, nothing whatever shall be added to or taken from the powder obtained by grinding the natural bituminous rock. Should it be proposed to use an asphaltic sandstone only, which contains more than 9% of natural bitumen, of such a consistency that the resulting pavement would prove too soft to sustain traffic, the material, if satisfactory in other respects, shall be made to conform with the requirements of these specifications by the addition of inorganic dust, in such manner and in such proportion as the Engineer may direct. The powder shall contain from 9 to 12% of natural bitumen.

"This powder shall be heated in a suitable apparatus to 93° to 121° C (200 to 250° F), and must be brought to the ground at a temperature of not less than 82° C (180° F) in carts made for the purpose, and carefully spread as specified for refined asphalt pavement, to such a depth that, after having received its ultimate compression, it

will have a thickness of 2½ in when laid on concrete. When the foundation is other than concrete it shall be laid on a 1-in binder course as heretofore prescribed, and the net thickness of the rock asphalt wearing surface after compression shall be 2 in. The surface shall be rendered perfectly even by tamping, smoothing, and rolling with heated appliances of approved design."

Specifications Proposed in 1911 by the Assn. for Standardizing Paving Specifications. "The bituminous rock or rock asphalt for use in the wearing surface must be ground to such a fineness that its mineral aggregate, after being freed from the bitumen by the use of carbon disulphide, shall all pass a 4-mesh sieve. The wearing surface made of the bituminous rock or rock asphalt must contain between 9.5 and 12.5% of bitumen soluble in carbon disulphide. The ground rock asphalt shall be heated separately to not over 177° C (350° F) or below 121° C (250° F). These heated materials shall then be combined and thoroly mixed in an asphalt mixer in the required proportions to produce a wearing surface complying with the above specifications. The mixture prepared in the manner above described shall be brought to the streets in carts at a temperature between 107° and 163° C (225° and 325° F) and shall be laid as specified in the specifications for sheet-asphalt paving."

29. Construction Cost Data

These vary so much with the price of the raw material and the manner in which it is manipulated that it is impossible to give any typical statement. Street labor is about the same as in sheet-asphalt. Plant labor is usually somewhat less. Superintendence, etc, is about the same. Cost of plant, interest charges and depreciation depend upon the kind of material used and the method of manufacturing it. Given the price of the raw material at any given point, the cost of the pavement may be calculated in the same manner as given under sheet-asphalt.

30. Methods of Maintenance

In European limestone rock pavements defective material is cut out down to the foundation and replaced with new material and the surface heater method of repairing is not used. This practice is usually followed in bituminous sandstone pavements but there would appear to be no reason why in certain instances a surface heater could not be successfully employed.

Guarantee Periods. In the United States these are usually the same as for sheet-asphalt pavements; that is, 5 years, altho some of the European cities call for a 2 years' free maintenance period and pay a definite sum per annum for maintenance during the succeeding 15 years.

SECTION 18

WOOD BLOCK PAVEMENTS

BY

GEORGE W. TILLSON

CONSULTING ENGINEER TO THE PRESIDENT OF THE BOROUGH OF BROOKLYN, NEW YORK CITY

GENERAL DATA

1. Historical Development

Russia. The first wood block pavements are said to have been laid in Russia several hundred years ago. The blocks were hexagonal in form and laid with a certain amount of care, but, as they were not used to any great extent or for any length of time, very little information is obtainable about them. In Petrograd, in 1912 there were in the city 689 000 sq yd of wood pavement, which is 6% of the entire pavement area.

In London the first wood pavement was laid in 1839; this consisted of hexagonal blocks of fir, some 6 to 8 in wide and 4 to 6 in deep. The blocks were laid on a foundation of gravel that had previously been rolled. They were bevelled or grooved on the edges so as to afford a foothold for the horses. The first pavements were not successful, but others soon followed, and the Engineer of the Sewer Commission stated, in a report made in 1874, that, counting the size of the blocks as constituting a difference, there must have been more than two dozen different kinds of wood pavements experimented with in the city previous to that time.

A system, known as CAREY'S consisted of blocks 6½ to 7½ in wide, 13 to 15 in long, and 8 or 9 in deep, the sides and ends having projecting and reëntering angles, locking the blocks together to prevent unequal settlement. Pavements of this kind were laid in 1841 or 1842. They required renewing, however, every 3 or 4 years. The dimensions of these blocks

were afterwards modified, and finally reduced to a width of 4 in and a depth of 5 or 6 in, the reëntering angles also being discarded.

The IMPROVED WOOD system was first adopted in 1871. On a subgrade, a bed of 4 in of sand was laid, and upon that two layers of 1-in deal boards, saturated with boiling tar, one layer across the other, were laid. The blocks were 3 in wide, 5 in deep and 9 in long. They were also dipped in tar and laid on the boards with the end joints closed, but the transverse joints were ¾ in wide, the space being maintained by pieces of boards nailed to the foundation and also to the boards. The joints were filled with rammed gravel, then a composition of pitch and tar was poured in until the joints were completely filled, when the surface was also covered with tar, gravel, and sharp sand. The foundation was somewhat elastic and maintained the even surface of the pavement as long as it was in shape, but when the pavement became pervious to water it settled and became rough and uneven. This was probably the first use of the tar and gravel joint for pavements of any description.

In 1872 a cement-concrete foundation was first used for a wood pavement. The concrete was 4 in thick and was laid by the Ligno Mineral Co. The blocks were of beech, mineralized by a special process, 3½ in wide, 4½ in deep, and 7½ in long, with the ends cut to an angle of 60°. They were laid with the ends inclining in opposite directions in alternate courses. In a few years, however, this form of block was abandoned for the rectangular, and fir was used instead of beech. The blocks were bedded in Portland cement and laid with joints ¼ in wide, partly filled with asphalt, and then grouted with mortar. It was thought after a few years' experience that the laying of the blocks directly upon concrete made so rigid a construction that the blocks wore more rapidly under traffic than they otherwise would. There were several means devised for overcoming this and making the pavement more elastic. The Asphalt Wood Paving Co. laid ½ in of asphalt upon concrete, and formed also the lower part of the joint with the same material, and the upper part with a grout of Portland cement and gravel. In addition to the elasticity, it was claimed that this also gave a perfectly watertight joint. One objection to this method, however, was that the asphalt softened under blocks when the weather became hot, allowing them to settle unevenly under traffic, making the pavement generally uneven and consequently causing abnormal wear.

In HENSON'S method the blocks were laid close, with a strip of roofing felt from 1/16 to 1/8 in thick, cut to the same width as the depth of the blocks, laid between each course. The joints were thus closed as completely as possible, leaving only the actual fabric of the felt, the material support of the blocks saving them from the rapidly destroying action of spreading at the edges. The protection of the wood was further enhanced by a layer of similar felt over the whole surface of the concrete foundation upon which the wooden blocks were cushioned. Another object of laying the felt between the blocks was to take up any longitudinal expansion that might occur on account of the changes of the atmosphere. It was thought that the felt would be thick enough to provide for the expansion of any one course of blocks. The results justified this method, which was somewhat expensive, but the endurance of the blocks was said to be increased from one-half to two-thirds by this freedom from the joining of the blocks and the mutual support of the edges. In order to provide for the transverse expansion a space of 1 or 1½ in was left along the curb and filled with asphalt and sand or gravel. In some cases, however, the row of blocks

next to the curb was left open until the greatest amount of expansion had taken place, and then filled in. The kind of wood used in London at that time was generally Swedish deal, and the blocks were generally laid without any chemical treatment, since that was considered of doubtful advantage, and as they wore out under traffic rather than failed from decay. It was not thought that creosoting or similar treatment would benefit the wearing qualities.

In 1874 Haywood made an extensive report to the Commissioners of sewers of London upon the comparative merits of wood and rock asphalt pavements. At that time there were but 12 238 sq yd of wood pavement and 30 802 sq yd of rock asphalt, quite a portion of the area previously laid with wood having been replaced with rock asphalt. In a table which he presented at that time he gave the actual life of wooden pavements that had been laid at different times since 1841 as varying from 5 years and 5 months to 19 years and 1 month. The pavement having the longest life, strangely enough, was the first one laid of those in the table. The average cost per square yard during life, including repairs, varied from 1s. 5¼d. to 3s. 4d. (35 to 81 cents), which last pavement had a life of 12 years and 3 months. He gave the average life of the pavements in the three streets of the largest traffic as 9 years, and those of the least traffic as 11 years and 3 months. His conclusions on the whole were more favorable to rock asphalt than to wood, altho the experience with rock asphalt at that time extended over a period of only 5 years, but later experience has justified his conclusions. London and Paris at the present time are using wood as a paving material, because it is less noisy than stone and less slippery than rock asphalt. On London Bridge, King William St., blocks wore 2⅝ in in 3 years and 2 months. Haywood estimated in general that the wear of wooden pavements would be from 0.2 to 0.3 in per year, under traffic of from 300 to 600 vehicles per yd for 12 hr.

In 1884 the wood pavements in London consisted generally of blocks 3 in wide by 6 in deep by 9 in long, altho the dimensions of length and depth varied somewhat.

Paris. Wood pavements were not used in Paris until 1881, but increased very rapidly, so that in 1911 Paris had 2 300 000 sq yd of wood pavement, which represented 21% of the entire pavement of the city. In Paris the blocks are laid on the heavy traffic streets, that is, streets where the bus and cab traffic is excessive. The material used at the present time is principally pine from the Landes and Swedish deal.

Germany. The total amount of wood pavement in Germany was reported in 1913 to be 1 085 968 sq yd, or 0.62% of the total amount of pavements in the different cities. About five-ninths of this pavement was laid with soft and four-ninths with hard woods, on a concrete base from 7 to 8 in thick. The blocks were 5.1 in deep, and, when impregnated by dipping, the pavement cost $4.06 per sq yd, with a 5-year guarantee, and $4.875 when the blocks were creosoted, with a 10-year guarantee.

Berlin has about 9 miles of wood pavement out of a total of 464½ miles. This city is practically level, the central business portion of it being paved almost entirely with rock asphalt. The River Spree runs thru the city, and there are many bridges over it. Wood pavement is used almost entirely on the approaches to these bridges, and also on the bridges over the railroad tracks. This is because the European rock asphalt is more slippery than the European wood, the reverse of what is found in this

country. The average life of the soft wood pavement in Berlin is taken as 12 years, and the cost of repairs about 17 cents per sq yd.

Quebec. Tamarack pavements have been laid in Quebec since 1855. The blocks are laid on a wooden flooring of 1½-in boards, laid longitudinally and crossed at right angles by a second flooring of 1-in boards so as to conform more readily to the crown of the pavement. Upon this flooring blocks about 12 in long, sawn from logs 10 to 15 in in diameter, are laid on end. In the spaces between the blocks small pieces of wood are forced, and the remaining interspaces filled with a grout made of sand, cement and tar, or sometimes a mixture of finely sifted coal ashes and cement. These roadways are very durable, it being stated that pavements, after having been in use 35 years, were taken up, when the blocks showed no signs whatever of any decay, but had been worn to one-half their original depth. These pavements cost from $1.55 to $1.75 per sq yd.

Boston, New York City and Philadelphia. In the United States the first wood pavements were laid about 1839, in Boston, New York and Philadelphia. No special care was paid to the character of the wood of which the blocks were made or to the method of laying, and they received no treatment whatever. It is not surprising, therefore, that the blocks soon decayed, and the pavement got into such disrepair that it had to be relaid.

A Committee of the Franklin Institute of Philadelphia in 1843 stated in a report that "The hexagonal hemlock pavement laid some years ago in Chestnut St., between Fourth and Fifth, cost $2.50 per sq yd, and was decayed to such an extent as to require renewal within 3 years. The squared-block wood pavement in Third St., of Northern spruce, cost about $2.25 per sq yd, and after 3½ years' use the hemlock portion of it was very much decayed and needs renewal, while the heart yellow-pine portion is still in apparently good order, although presenting strong symptoms of decay. This pavement was laid in Sept., 1839. Finally, in consequence of the slippery nature of their surface, their deficiency of durability when of ordinary timber, of their expense in the ultimate, and in view of results of experience as far as they have become known to us, we are reluctantly impelled to the conclusion that, tho their use may be proper in some detached situations, wooden pavements ought not at this time to be recommended as part of the general system of paving by the city of Philadelphia." The Committee also stated that the authorities of New York had determined to take up the wood pavements and relay them with stone, and that the experience of Boston had been practically the same as that of Philadelphia and New York City.

Washington, D. C., is a city in which experimental pavements of many kinds are laid. The Board of Public Works was appointed in 1871, and at that time 100 000 sq yd of wood pavement had been laid in Washington and Georgetown. The exact type is not known, but probably quite a large proportion of it was the Nicholson, as that had been laid in many cities previous to that time. Subsequent to 1871, and under the authority of the Board of Public Works, there were laid in Washington over 1 000 000 sq yd of wood pavements, under twelve separate patents; they cost from $2.00 to $4.20 per sq yd. They soon began to decay and to be replaced, so that between 1875 and 1878 over 315 000 sq yd had been removed. From this time they were replaced gradually by other material until 1887, when 18 403 sq yd only were left, and these were removed in 1889.

In a report to the Engineering Department in 1887 the Commissioner says: "Cedar block pavements used so extensively thruout the Northwest are cheap, $1.00 to $1.30 per sq yd, but deteriorate rapidly, are objectionable on sanitary grounds, and are anything but smooth for street wear. Creosoted wooden blocks, with a hydraulic cement foundation, when closely laid, approach nearest to the ideal block pavement. Those in the form of the blocks of the Ker Pavement Co., New York City, are a fair

example of this class. These are laid with creosoted wood blocks, 6 by 9 by 8 in in dimension. The wood fiber is placed vertically to a depth of 6 in; ⅝-in joints are left which are filled, 1 in with hot asphalt and 3 in with Portland cement grouting. The resulting pavement is clean, noiseless, smooth, and not slippery." Altho this pavement received so great an endorsement, it was not used to any extent.

Nicholson Wood Block Pavement. Wood pavements, however, came into use very generally in the United States between 1860 and 1870, laid under the Nicholson patent. Probably the best idea of this pavement can be obtained by quoting from the Brooklyn, N. Y., specifications in a contract made in 1869:

"The wooden blocks of the Nicholson pavement are to be of sound white pine or southern yellow pine, sawed so as to be 3 in thick and 6 in long; the blocks for paving the kennel to be sawed to a uniform level so that a channel-way for surface water will be formed outside the curb-lines. The flooring for blocks, and the pickets to be used between each transverse course of blocks, to be of sound common pine boards, conforming to 1 in thickness, the whole 2 in wide and 1 in thick. The foundation or sand bed which is prepared is to be brought to a proper crown and width to the street edge and then covered with sound common pine boards of the dimension described, paved lengthwise to the line of the street, the ends resting on similar boards laid transversely from curb to curb; the flooring to be well and thoroly tarred on both sides with hot coal tar brought to the proper consistency with paving cement, so as to be tough and fibrous and not brittle when cool. Upon this floor of plank the blocks are to be set on end in parallel courses, transversely with the line of the street; each block before laying to be dipped to half its height in hot coal tar and paving cement prepared as described; each course to be separated by a course of pickets placed on the face of the blocks and to be properly nailed; the space between each course of blocks about the pickets to be filled with clean roofing gravel and hot coal tar, and then the cement thoroly mixed and compactly rammed by means of a paver's rammer and an iron blade made to fit the interstices or spaces between the blocks; the gravel to be very thoroly dry and warm, so as not to chill the tar; the coal tar in all cases is to be boiled down and so thickened with paving cement as to be tough and fibrous when cool and not brittle even in cool weather, and is to be applied hot and in such quantity as will thoroly penetrate and fill all the joints; the whole surface of the pavement, as rapidly as the grouting shall be completed, is to be covered with hot tar and paving cement as above specified, and then covered with fine sand and gravel and not less than ¾ in thick."

The Nicholson pavement in Brooklyn, N. Y., cost $4.50 per sq yd, with an additional sum of 50 cents per sq yd for grading the street and preparing the foundation. The blocks for this pavement could be either treated chemically or not, according to the belief of the special set of authorities in control, but as a matter of fact they were laid without treatment. This pavement, when first laid, was very smooth and presented a pleasing appearance to the eye, and for a time was extremely popular. It soon began to decay, however, and was rough and uneven unless frequently repaired, and, as the decay continued, became unhealthy and unsanitary. Its average life in Brooklyn, N. Y., was about 6 years; in St. Louis 5 years and 6 months. Memphis, Tenn., laid a large amount of this pavement, but it soon decayed, requiring relaying with entirely different materials.

Alexander, Miller & Co.'s Improved Wood Pavement, which was very similar to the Nicholson, was laid at about the same time. The principal difference between this and the Nicholson was in the shape of the blocks, which were sawed on a bevel so as to be 4 in thick at the base, 3 in thick at the top and 6 in deep, so that when set together at the bottom they left an open joint 1 in wide at the top. In Brooklyn these blocks were laid on burnettized spruce planks 1½ in thick. These planks were laid lengthwise of the street, resting on similar planks laid transversely from curb to curb. The spaces between the blocks were filled with coal tar

and pitch, and the surface of the pavement was covered in the same way as that prescribed for the Nicholson pavement. This pavement cost in Brooklyn $4.90 per sq yd, and its life was practically the same as that of the Nicholson.

Round Cedar Block Pavements. Between 1880 and 1890 all Western cities had a rapid growth, and consequently there was a great demand for street pavements. These cities, being far from the supplies of stone, naturally took kindly to the representations of the agents for wood pavements, as the pavements were cheap, and it was hoped that the property on the abutting streets would be sold before the pavements required relaying. These pavements were ordinarily known as cedar block pavements. This material came from the North, and was especially cheap in Chicago and Detroit, where water transportation could be had, but it was also laid in Omaha, Neb., and in the larger cities of Iowa. The blocks were made from cedar posts, from which all the bark had first been removed, and sawed into pieces 6 in long, by gang-saws cutting from six to eight blocks at once. These blocks varied in diameter according to the dimensions of the posts, but the specifications generally called for them to be from 4 to 8 in in diameter, or, if larger, the blocks were split before being laid in the pavement. They were laid on different foundations such as sand, sand and gravel, sand and broken stone, sand and hemlock boards, and concrete with a sand cushion. The great and almost only merit of these pavements was their cheapness. They were quickly laid, and, when new, made a pleasing and apparently satisfactory roadway. The blocks were laid on the foundation very simply, the only object being to get them close together so as to form as small a space as possible between the individual pieces. The blocks were rammed and the space filled with clean, coarse gravel previously heated and dried, and then poured full of paving cement composed of coal tar pitch, the specifications generally requiring 2 gal per sq yd. Between 1880 and 1890 many millions of yards of this pavement were laid in the cities of Chicago, Detroit, St. Paul, and Minneapolis, Minn., Omaha, Neb., Kansas City, Mo., and many other smaller cities thruout the Central West. The pavement being cheap and all of these cities at that time having an unprecedented growth, a much greater amount was laid than would have been laid under ordinary circumstances, as the real estate boomer desired to have a paved street in front of his property long enough to sell it, no matter what might be its eventual life. This pavement lasted ordinarily about 5 years in good condition, when the decay was generally so great as to make it rough and undesirable for travel, and in a few years more it became practically impassable and required renewal when it had been down 7 years.

Chicago probably had more cedar block pavement than any other city. On Jan. 1, 1897, there were 752.68 miles of this pavement, and during the year there were laid 23.53 miles. On January 1, 1900, the mileage was 763.21. In 1897 the average cost of this pavement laid on a plank base was 70 cents per sq yd, and when laid on 6 in of broken stone, 85 cents per sq yd. The City Engineer said at that time: "The plank foundation is considered to be the best, as the wearing surface is more even, and the planks last as long as the blocks, and whenever the pavement is renewed the street is torn up, as, for instance, by the gas company renewing the calking of their pipes, and the city laying new conduits. In such cases it is necessary to relay the macadam." On Jan. 1, 1911, the cedar block pavement in Chicago had been reduced to 273.59 miles, and on Jan. 1, 1915, to 214.55 miles.

Detroit also laid a considerable quantity of this pavement. Both this city and Chicago, however, recognized that it was a temporary pavement only, but with its low cost it was considered to be, under the circumstances, an advisable proposition. A small amount of this material was laid in Detroit in 1914; the blocks, however, were only 4 in deep and laid on concrete, so that when they did decay the base would remain in good condition and at proper grade, and it could be economically refaced with a new pavement. The following are the specifications for the 1914 pavement:

"**Cushion.** To secure a smooth surface to the pavement there shall be spread by means of a template, shaped to conform to the true cross-section of the street, when compacted and rolled with a roller weighing not less than 200 or more than 300 lb, 1 in of clean bank, lake or river sand free from all loam or foreign matter. The sand must pass a ¼-in screen. On streets having car tracks a mortar cushion shall be used, composed of one part Portland cement and four parts fine river sand, said cushion to extend 2 ft outside of track.

"**Cedar Blocks.** Cedar blocks shall be 4 in long, of the best quality of sound, selected, live timber, stripped of all bark and free from all traces of rot or indications of decay, and shall not measure less than 4½ in nor more than 9 in in diameter, and shall be so selected in size as to make as close-jointed a pavement as possible. The contractor must furnish all labor to cull the blocks under the supervision of the Commissioner of Public Works or his representative. All condemned blocks shall at once be removed from the street.

"**Filling.** The spaces between the blocks shall be filled with screened gravel or crushed granite or boulders of size varying from ½ to 1 in in diameter and free from dust, sand, loam or thin stone, screened when necessary, thru a wire screen, to set at an angle of 60°, with meshes not less than 8 in lengthwise by ½ in in width; tamped with iron tamping bars and refilled and retamped as often as required by the Commissioner of Public Works or his representative, and then the surface shall be well rolled by the city roller at a cost to the contractor of ½ cent per sq yd. After rolling, the spaces between the gravel or stone filling of the blocks shall be completely filled from the bottom to the top with paving cement obtained from the direct distillation of coal tar, and shall be the residuum thereof, such as is ordinarily numbered 5 or 6 at the manufactory, or any other approved composition. The quality of the composition, and the temperature at which it shall be heated, shall be satisfactory to the Commissioner of Public Works. Extra material and care shall be used at the gutters in filling all joints, in paving around catch-basins, or other receptacles, to effectually prevent the leakage of any water into the sub-roadway; all joints to be completely filled to the top before adding top dressing. No teaming shall be permitted over the pavement until the spaces are filled as above specified."

In 1888 many of these cities laid pavements practically the same as those just described, except that the material was cypress from the swamps of Arkansas. This wood was much heavier than cedar, more dense and compact, and, from its appearance, should be more durable, but there is probably no material produced by nature about which as little can be ascertained by a preliminary examination as wood. The only sure way to find out its durability is by experience. In an actual test for abrasion, cypress would probably have outlasted cedar, but as far as decay from the atmosphere was concerned it was much shorter-lived, and the cypress blocks had not been laid more than 2 years before they began to show serious signs of decay. This in itself proved beneficial, as it prevented a larger amount from being laid. While heart cypress has deservedly a good reputation for durability, the sapling wood in all of these instances plainly showed itself of no value. One street in Omaha which was paved with cypress blocks in 1888 was repaved with brick in 1892, and the other streets paved with the same material had about the same life. When the Tenth St. viaduct in Omaha was completed in 1889, it was decided to pave the roadway with cypress blocks; but in this instance the inspector went to

the Louisiana swamps to see the timber cut and sawed, selecting only the best trees, so that the best results could be obtained. Despite this precaution the pavement lasted but 9 years.

In San Antonio, Texas, a certain amount of mesquite blocks, hexagonal in form, were laid at quite an early date and as late as 1914. In 1889 the City Engineer of Galveston, Texas, where pavements of this material had been laid, wrote as follows:

"We have some creosoted pine blocks from 6 to 10 by 4 by 6 in. About 75 000 sq yd were laid in 1874, which, even now, except where the pavement has been disturbed for street-car tracks, gas and water pipes, is in good condition. The blocks were laid at right angles to the sidewalk curbs on a sand foundation, with a 1-in space between, which space was filled in with a wedge driven down about 2 in below the top surface of the blocks and penetrating about 2 in into the foundation below the bottom of the block, the space above the wedge being filled with tar and gravel, and in 1892 to 1895 inc. there were laid some 4 or 5 miles of creosoted pine block pavement. In this instance the blocks were laid touching without any wedges, and tar was spread over the top, and sand over the tar. This last pavement has given endless trouble by swelling and buckling, and kicking out the sidewalk curbs after every rain, especially when the rain followed a dry spell. I relaid a couple of blocks, about 3500 sq yd, with wedges and tar and gravel with some of the displaced blocks about a year ago, but it is beginning to show distress. We have some cypress blocks, laid with wedges some 10 or 15 years ago, that did good service for 8 or 10 years, but they are now rotten and in a very unsanitary condition. If enough oil is put in pine blocks to prevent swelling, I am satisfied that they would make excellent paving material. They have a wonderful ability to resist abrasion."

Preservative Treatment. Experience demonstrated plainly that if wood was to be used as a paving material in the United States, it would require chemical treatment. Indianapolis, Ind., was the first city in the country to lay pavements in this manner. The first wood pavements laid there, however, were of red cedar rectangular blocks from the State of Washington, without any treatment. The blocks were laid with close joints, on a concrete base, with a 1-in sand cushion, but they soon showed wear and in a short time began to decay. In 1896 four streets were paved with the same material, except that the blocks were creosoted. The blocks were 4 in wide and 5 in deep, laid at an angle of 45° with the curb. The joints were laid close, and no provision was made for expansion at the curb. Some trouble was experienced on account of the blocks bulging, mainly with the untreated blocks, but some with the creosoted blocks, so that the Board of Public Works adopted long-leaf yellow pine for the material and treated the blocks with creosote oil. The blocks were laid as before described, except that a space 1 to 2 in wide was left along the curb for expansion; this space was filled with sand and covered with paving pitch. The interstices between the blocks were partially filled with fine, dry sand, when the entire surface was rolled smooth, and then covered with hot paving pitch and fine gravel screenings. These pavements cost from $2.10 to $2.50 per sq yd. But little was known at that time of the treatment of blocks or of the character of the oil.

The specifications in Indianapolis in that respect read as follows: "After the blocks have been inspected and found satisfactory, they shall be placed in an air-tight chamber, where, by means of superheated steam and the use of a vacuum pump, all sap in the blocks shall be vaporized and then removed. When the blocks are thoroly dry, and while the cylinder is under a vacuum of 15 or 20 in, heavy creosote oil, weighing 8.8 lb per gal, shall be admitted into the cylinder and pressure added until the pressure in the cylinder shall be at least 50 lb per sq in. The blocks shall remain in the cylinder until they have absorbed 10 lb of oil per cu ft of timber and until the creosote has impregnated the timber uniformly thru the entire thickness of the blocks." The

joints were filled with paving cement composed of 10% of refined Trinidad asphalt mixed with 90% of coal tar paving cement distilled at a temperature of not less than 315° C (600° F). The surface of the pavement when completed was covered with ½ in top dressing of clean, coarse sand or granite screenings.

Creosote Oil and Rosin. The success of these Indianapolis pavements was such that promoters were desirous of extending them to the East, and a method of treatment was originated which provided that the blocks should be treated with a preservative composed of 50% of creosote oil and 50% of rosin. The idea of the rosin was that, as creosote is a very volatile substance, it was necessary to provide some means of keeping it in the blocks, and it was thought that by mixing it with the rosin that result would be brought about, and experience seemed to demonstrate that such was the case.

In 1900 the first pavement of this character was laid on Tremont St., in Boston, in front of the Common. The blocks were 4 in deep and 4 in wide, laid on a concrete base. When these blocks had been in use 14 years the pavement was in good condition and showed very little wear, and it had cost a very small amount for repairs.

In 1902, Brooklyn, N. Y., laid a pavement of this type as an experiment. It was so pleasing, however, and bid fair to be so satisfactory, that the following year specifications were drawn up and a considerable amount of wood pavement laid. In order to obtain competition, the specifications provided that the wood should be treated with a preservative composed of 50% of creosote oil and 50% of rosin or some other suitable waterproofing material. It was also specified that the blocks when treated should sink in water, and when dried for a period of 24 hr at a temperature of 38° C (100° F) they should not absorb more than 3% of water upon being immersed for 24 hr.

Coal-Gas Tar Oil and Water-Gas Tar Oil. On account of the increase in the cost of rosin, in the Borough of Manhattan, New York City, the specifications were changed to permit the preservative to be composed of 75% of creosote oil and 25% of rosin; and in 1909 a committee was appointed by the Board of Estimate and Apportionment of the City of New York, composed of the Chief Engineer of the Board, the Chief Engineer of the Department of Finance, and the Chief Engineers of the Bureaus of Highways of the different boroughs to draw up specifications for wood blocks. After many hearings, at which were present many manufacturers of blocks, the following specification was adopted and sent to the Board of Estimate and Apportionment, which approved it.

"The oil with which the blocks are to be treated shall be a stable, antiseptic and waterproofing oil from which the water has been removed by distillation, and which shall have a specific gravity of not less than 1.12 at 38° C (100° F). When distilled in the manner hereinafter described, the oil shall lose not more than 35% up to a temperature of 315° C (600° F). The distillate between 255° and 315° C (491° and 600° F) shall have a specific gravity not less than 1.02, the said specific gravity being taken at a temperature of 15.5° C (60° F)." It will be noticed that the requirement is made that the distillate between 255° and 315° C (491° and 600° F) shall have a specific gravity of at least 1.02. The reason for this was because certain manufacturers claimed that water-gas tar oil should be allowed as well as coal-gas tar oil. The committee was hardly willing to accept this, as it deemed that there had not been experience enough to demonstrate the merits of the water-gas tar oil, but felt that it could allow a mixture of the two if the amount of water-gas tar oil did not exceed 50% of the mixture, and with the specific gravity requirement of 1.02 for the distillate it was thought that an excess of the water-gas tar oil would be avoided. This was found to work out satisfactorily in practice.

Development in United States. Treated wood block pavement has rapidly come into use, so that on Jan. 1, 1914, there were 9 670 000 sq yd in the United States. Naturally there have been many differences of opinion as regards the specifications under which it should be laid, not only as to the character of the wood, but also as to the character of the preservative, and the amount to be used.

2. Characteristics

The 3rd Int. Road Congress held in London in 1913 adopted the following conclusions relative to wood block pavement:

" 1. Where gradients permit, wood block pavement is very suitable for streets where traffic is great, but is not of the exceptionally heavy character usually existing on streets near docks or similar centers of industrial traffic. It should be used where a noiseless pavement is desirable. It is of great importance that a concrete foundation should be laid of sufficient strength to carry the traffic passing over the pavement.

" 2. Great care is necessary in the selection of the proper timber for the purpose, and all soft wood blocks should be thoroly impregnated with a well-proved preservative before being laid.

" 3. In view of the varying results given by wood pavements, according to local circumstances, it is desirable that further investigations and laboratory experiments should be carried out in connection with the selection of the timber and of the impregnating preservative.

" 4. Every precaution should be taken in laying the blocks to prevent, so far as possible, the entry of water thru the joints. Hard woods give varying results according to local circumstances, and it does not appear desirable to recommend them for roads with intense traffic in large cities, unless some means are devised to effectively prevent the rapid destruction of the joints and the resulting destructive effect on the concrete below. If these woods are employed it is desirable not only to prevent the percolation of water thru the joints to the foundation, but also to consolidate the blocks as far as possible so that they may not become rounded at the edges. Soft woods obtained from suitable kinds of trees, and especially from resinous species, are equally suitable for roads with a comparatively heavy and intense traffic as well as for roads with a light and infrequent traffic. In the latter, however, the blocks are liable to rot if they have not been suitably pickled. It is also desirable to make the joints as small and watertight as possible. On the other hand, their comparatively rapid wear on roads with great traffic should encourage one to make exhaustive investigations into the best means of treating them, so as to increase their strength without prejudice to their elasticity.

" 5. Subject to certain precautions, such as impregnating of the wood, waterproofing of the joints and surface, frequent cleaning of the roadway, etc, there is no objection to wood pavement from the sanitary point of view.

" 6. The spreading of gritting is necessary under certain conditions and in certain weather, especially on hard wood paving, to prevent the surface becoming slippery, but the gritting should be done with suitable small gravel, chippings, or sharp sand, so as to avoid, as far as possible, any injury to rubber tires."

3. Crowns

A general discussion of the crown of a pavement is covered in Sect. 19. The principles elucidated there apply to wood block pavements with as

much force as to stone; in fact, even to a greater degree. This is because, with wood block, being more slippery than stone, it is important to have the side slope as slight as possible, so as to prevent the slipping of horses sidewise. It is also important because, however well blocks are treated, there must be a certain amount of swelling, and therefore compression, in the individual blocks. The pressure thus exerted has a tendency to lift the blocks from the concrete, and the greater the crown of the street the greater will be the tendency of the pavement to rise as a whole. For this reason, therefore, if for no other, it is desirable to have the crown of a wood block pavement as light as possible, and at the same time allow the water to run freely to the gutters.

MATERIALS

4. Physical Properties of Wood Blocks

The Essential Qualities of wood for a good paving block are somewhat similar to those required for stone, that is, the blocks should be hard and durable, and should not wear unevenly or be slippery under traffic. If the blocks are too soft, the wood is liable to wear rapidly, or the fibers crush, so that it becomes rough and uneven; if the blocks are too hard, the surface is slippery, and that is one of the main objections to wood pavement.

The Selection of the Kind of Wood to be used is especially important, not only because wood as a whole is becoming more expensive year by year, but if a wood can be found that is suitable and one that is generally scattered over the country, it will materially reduce the cost of the pavement by lessening the cost of transportation. Then, too, more competition can be had if a large variety of material can be used.

Long-Leaf Yellow Pine. It has generally been considered that long-leaf yellow pine, which is extensively used, makes the best paving blocks of any wood that has been used. This material is brought to the North only at considerable expense. It is a wood that is in great demand for other purposes, so that the extra call upon it for wood pavements tends to increase its price. It is extremely hard, and stands heavy traffic remarkably well, the greatest objection to it being its slipperiness under traffic and its liability to split. The former objection can be overcome by sprinkling with sand on special occasions, and the latter by making the blocks deeper; this of course adds somewhat to the expense. The structure of this wood varies greatly, and to secure a fairly uniform quality it is customary to specify the number of rings per inch. The strength of wood varies according to its dry weight: the heavier the wood, the stronger it is. The weight depends on the thickness and number of wood cells. It is found that the cells in the summer or dark rings are smaller and have heavier walls than the spring wood. A rule for quickly determining the quality of long-leaf pine has recently been published by the U. S. Forest Products Laboratory. It states that pine in which the cross-section of the summer rings shows an area of 33% or over of the total corresponding annual ring is stronger than pine where the percentage of summer wood is less. This rule automatically rules out wide grained material that is undesirable and permits such wide grained lumber as should be used.

Tamarack is a wood that has been very successful wherever used. It is found in limited areas and in limited amounts, so that it cannot be considered as available for many localities.

Black Gum has been used, but not as successfully as pine. It requires

a greater amount of treatment, but, as it is softer than the pine, it is not quite as slippery. In 1907 and 1908 it was used to a certain extent, as at that time yellow pine was extremely expensive, but in recent years it has generally been discontinued as a paving material.

European Hard and Soft Woods. In Europe the wood used as a whole is divided into two classes, namely, hard woods and soft woods, the soft woods being generally pine or some kind of fir, and the hard woods Australian Jarrah or Karri. The Australian woods are as a rule untreated. They are extremely hard and wear well, except that they break at the edges, becoming rough under heavy traffic. They are so dense that they do not take treatment well, and so decay irregularly, and become rough for that reason also. A pavement of this Australian wood was laid in New York City in 1895; it was expensive and gave no better satisfaction than American woods.

Tests for Wood Blocks. Wood has never received in this country any special tests for the determination of its characteristics for paving purposes, but in Paris it is tested in the laboratory for imbibition, thrust, resistance to compression, wear by attrition, and resistance to blows. The blocks are also tested in a rot pit, so called, to determine the efficiency of the various methods of preserving the wood. The rot pit consists of a pit filled with manure into which the blocks, both treated and untreated, are buried from 18 months to 2 years, when they are taken out and examined. No other place is known where such tests are made.

Service Test Pavements. In 1906 an experimental pavement made up of different varieties of wood was laid by the Forest Service of the U. S. Dept. of Agr. in Minneapolis, Minn. For a complete description of the pavements and the results after 6 years' service, see the report by the Forest Service (44).

Description. The woods used in the improvement were long-leaf pine, Norway pine, tamarack, Douglas fir, western larch, white birch and hemlock. The long-leaf pine was included so as to provide a standard for comparison with the other varieties. The blocks were treated with 16 lb per cu ft of coal tar oil having a specific gravity of 1.09 at 20° C (68° F), except that the oil used in the white birch and western larch blocks had a lower specific gravity, so that 20 lb per cu ft was used in the case of these species to compensate as nearly as possible for the discrepancy in the specific gravity between the oil used and that specified.

1912 Report. The conclusion reached upon an examination of the pavements by the government authorities, 6 years after it had been laid, was that: "The species will be tentatively grouped in accordance with the results of this inspection in the order of their value for creosote oil paving material as follows: (1) Long-leaf pine; (2) Norway pine, white birch, tamarack, eastern hemlock; (3) western larch; (4) Douglas fir."

In the **1914 Report**, covering the result of the fourth inspection, the order of efficiency of service according to species was practically the same as given above. The report goes on to say, however: "The most noteworthy result shown by this comparison is the sudden increase in the areas of local depressions below the general level of the sections, noted at the 1913 inspection, in all but the long-leaf pine and white birch sections. This was especially prominent in both larch sections, as noted first in the 1913 inspection. These two sections are rapidly becoming unserviceable. In 1910 depressions ½ in or more in depth were reported only in the Douglas fir sections which were replaced in 1911. In 1912 these depressions had appeared to a greater or less extent in all but the long-leaf pine, while by 1913 all sections showed considerable areas of deep depressions. The sections of white birch and long-leaf pine were all in about the same condition and were in much better shape than any of the other species. Eastern hemlock and tamarack had about the same percentage area of depressions and average wear and were in considerably better condition that Norway pine. Both of the western larch sections were in unsatisfactory condition, 25% and 35% of the areas, respectively, being below the general level of the pavement. These depressions

were very numerous and rendered the pavement rather rough. The deterioration of the larch blocks from now on will unquestionably be very rapid on account of these depressions. Blocks removed during the inspections were badly broomed and shattered."

Francis Wood's Specifications (9). "The timber from which the blocks are to be cut shall be carefully selected fourth Swedish, close grained, yellow deals, bearing the shipper's mark, and which must be described in the current Timber Trades Journal List. The annular rings shall not be less than 10 to the in, not more than 2 in of sapwood shall appear in any block, and the percentage of such in bulk shall not exceed 15. They shall also be free from large, loose or dead knots, shakes, or other defects, and shall not contain more than 5% of waney edges. Timber that has not been properly stored and become dry will not be accepted."

London Specifications: "It must be of a heavy resinous nature. Blocks showing blue sap or discolored wood will not be accepted. The blocks must be cut perfectly true in shape and size of the full specified depth after sawing, and free from large, loose or dead knots, waney edges, warps, shakes and other defects. One surface of every block must be free from knots."

Chicago Specifications: "All blocks shall be made of sound timber and shall be free from any defects which will be detrimental to the life of the block or interfere with the proper laying of the same. Each block shall have at least 66% of heart wood. The blocks shall be carefully protected from the effect of the sun and weather before and after treatment and until laid. The timber shall be that known to the trade as prime timber and of a texture permitting satisfactory treatment as hereinafter specified, and shall be subject to inspection at the works in the stick or at any time during the process of preparation or thereafter. The timber shall be sound, square-edged, free from bark, shakes, large or loose or rotten knots, red heart, worm or knot holes, or any other defects which will be detrimental to its strength or durability. No second growth timber or loblolly pine will be accepted. With southern yellow pine timber, the annual rings in the 3 in measured radially from the center of the heart shall average not less than 8 to the inch."

5. Size of Blocks

The principles governing the size of blocks are somewhat the same with wood as with stone, but they vary somewhat as regards the depth and the width. As timber is gotten out in exact sizes, it is a simple matter to specify the width of the blocks, they being cut from stock sizes of plank, and the same is true to a certain extent of the length of the blocks, as that corresponds to the width of the planks.

Width and Depth. The widths used in the United States are 3 in and 4 in, planks of this thickness being common for sale. Just which is the better width in a pavement is somewhat uncertain, altho it is believed that there is no very material difference. Three-inch blocks give more joints in the pavement, and for that reason afford a better foothold for horses; at the same time the greater number of joints gives more opportunity for wear, and on that account the narrow width is objectionable. The ordinary depth of blocks, too, is 4 in, and as, if the blocks are of the same width and depth pavers will invariably lay a few of them on the side, it is not advisable to have the width and the depth the same; so that, if a block with a width of 4 in is used, it is better to have the depth of the block 4½ in in order to avoid mistakes. It is remarkable how quickly a block laid flat can be picked out from the pavement at a glance, on account of the extra wear caused by the traffic coming upon the side of the fiber instead of upon the end. So far as actual wear is concerned, a block 3 in deep would undoubtedly last for 20 or 25 years on a residential street, but it is necessary that the pavement have a certain stability, which it cannot obtain with a shallow block, and a certain strength in the block itself, not only to sustain the weight of a load, but also to prevent its moving laterally, as it is un-

doubtedly a fact that a shallow block will expand much more easily than a deep one. In the United States, for ordinary streets, the depth is generally made 4 in, but sometimes on light traffic streets 3½ in.

In London the practice is to lay blocks 4 or 5 in in depth, but it must be remembered that the blocks used there are of softer material than American pine, and also that the traffic is much more severe. Four-inch blocks were being used in London in 1913, and the blocks previously referred to as seen on the Waterloo Boulevard, in Brussels, were only 3 in deep. Both the Paris and the London blocks wear down very appreciably before being replaced.

English Practice. Wood (9) states that the wear of best Swedish soft wood pavement in England is 0.061 in per annum per 100 tons per ft of effective width of roadway per day; and allowing a permissible total wear of 2.2 in, by figuring backwards he obtains the life of the pavement. So that he deduces that, when the traffic is equal to 3 000 000 tons per annum over an effective width of roadway, the life of the pavement will be 10.8 years. In speaking of the depth of the blocks he says: "The depth of the blocks is usually 5 in, but there is no reason why 4-in blocks should not be used in lighter trafficked roads. The method of selecting the depth of the block may be obtained by limiting the life of the proposed pavement to 12 years in the case of heavy traffic over 300 tons per ft width, 15 years over 100 tons per ft width, and 20 years under 100 tons per ft width. For example: Suppose the traffic was found to be 100 tons per ft width per day; the rate of wear would be 0.0615 in per annum; this multiplied by 20 equals 1.23 in, which added to 2.75 in equals 3.98 in. In this case a 4-in block would be sufficient. Any less depth than 3½ in off the saw would not be economical, and similarly, as may be gathered, any greater depth than 5 in would not give any greater satisfaction than a 5-in block." The above conclusion is evidently based upon 2.75 in as the minimum depth to be allowed a block under wear.

6. Preservatives

It is generally admitted that wood must have some chemical treatment if it is to be successfully used as a paving material. Wood has been treated chemically, in order to preserve its life in different structures, for many years. Many different kinds of treatment have been used and different chemicals employed, but the results have been such that it is generally considered by engineers at the present time that creosote oil manufactured from coal tar, all things considered, is the best. The object of the treatment is not only to prevent decay but also to keep the block stable, so that it will not expand too much in wet weather, or shrink and become loose in dry weather. For this reason the same principles will not prevail as if the material was to be used where preservation of the timber only was to be considered, as in piles, railroad ties, etc.

Required Life of Creosoted Wood Blocks. In most American cities the traffic on streets where wood would naturally be used is such that the blocks will wear out only after many years of use, so that a preservative is required that will not only preserve the wood for 5 to 25 years, but for even 40 years. If a block can be treated so that decay will be prevented for that length of time, there is no doubt that on the ordinary residential street in the ordinary city a wood pavement, properly laid, will last 40 years. A portion of Clinton Ave., Brooklyn, N. Y., was paved in 1903 with wood blocks; in the winter of 1913–1914 a portion of this pavement was taken up and exhibited at the Forest Products Exposition in New York. The blocks were found to have sustained a wear of only ¼ in. The traffic on the street was much more than that which would be had on the ordinary residential street, fully equal to the traffic on a good retail business street.

The Advantages of Creosoting (13) are as follows:

"1. A physical action: By the treatment a very greatly increased solidity

is effected by choking the pores of the wood, making it more solid, so that subsequent absorption of moisture is prevented to a great extent.

"2. A physiological action: The creosote imparted to the wood prevents germinal life, which would otherwise destroy the timber, as it developed within it. The preservatives used are chloride of zinc, sulphate of copper, etc, their action depending principally on their toxic properties. Creosote, however, it is stated, has the advantage of a well-marked smell which most of the lower animals dislike.

"3. A chemical action: The tar acids are not only antiseptic, but they possess the power of coagulating albumen. This latter action plays a very important part in the preservation of timber."

Kind of Preservative. Since 1910 there has been a great deal of discussion as to the nature of the creosote oil to be used, especially as to its specific gravity, some people claiming that an oil of a gravity of 1.03 or 1.05 should be used, as it would penetrate the blocks much more easily than the heavier oil, and that it is easier to obtain; others claim that the heavier oil should be used, as it is possible to get a satisfactory treatment with this oil and that it will remain in the blocks much longer than the lighter oil. This is a theory that has generally been accepted by engineers, as is shown by the specifications adopted.

The Function of the Preservative Treatment for wood paving, according to Hill (25), is to accomplish the following results: (1) Preservation from decay. (2) Mechanical filling of the pores, to prevent the absorption of fluids, which further accomplishes: (a) Elimination of expansion; (b) increase of resistance to wear; (c) maintenance of sanitary value. Creosote oil seems to meet these requirements better than any other preservative commonly used. The other preservatives are mostly water solutions, which are easily leached out of the wood, and thus lose their preservative effect. Moreover, being themselves largely composed of water, they do not prevent expansion in the blocks, do not increase their resistance to wear, and do not maintain them in a sanitary condition. The same requirements which have caused creosote to supersede other preservatives in wood paving call for a larger proportion of high distilling constituents in the creosote than is necessary in the preservation of timber for many other purposes."

Essential Qualities of Creosote Oils, as stated by Church (15b), are as follows: "It must be reasonably non-volatile in character, so as not to be rapidly lost by evaporation. It must be of sufficiently low viscosity at the temperature of impregnation so that the wood will not offer undue resistance to diffusion and penetration. It must be homogeneous in character, so that at all times a uniform product may be obtained. The chemical requirements of the oil should be as follows: It must be entirely insoluble in water, so that it will not be washed out of the wood, and so that it will resist to the highest possible degree the entrance of moisture into the treated fiber. It must be sufficiently antiseptic in character to preserve the wood against decay during the period of the mechanical life of the block."

Water-Gas Tar Creosote, according to Weiss (7), "may be produced which, on fractional distillation, will display a great similarity to coal tar creosote. There is a difference, however, in the constituents of the two creosotes, as shown by the difference in certain physical properties of fractions distilled from them at equal temperatures. Furthermore, water-gas tar creosote is distinctive in the absence of phenols and cresols, and usually in the presence of hydrocarbons of the paraffin group; it is not so antiseptic as coal tar creosote. Unfortunately, quantities of this oil are mixed with coal tar creosote, so that it is often impossible in practice to detect its presence. While this oil undoubtedly has considerable merit as a preservative of timber, there is not sufficient precise data available to warrant giving it the confidence which the coal tar product now enjoys."

Coal Tar Creosote, opinion by Weiss: "Tests made at the U. S. Forest Products Laboratory show the toxic limit of coal tar creosote to be between 0.2 and 0.4%. Very small amounts of it therefore protect wood from decay. In general, the lighter fractions are more toxic than the heavier fractions. They are also far more volatile

and when injected into wood by themselves evaporate at a rapid rate. The heavier constituents of coal tar creosote are therefore, in addition to being slightly toxic, of direct value in helping to retain in the wood these lighter oils."

Von Schrenk (45d) says: "It will not be necessary to dwell on the history of the use of coal tar creosote, nor to present proofs as to its value as a wood preservative. For years this substance has generally and justly been regarded as the best wood preservative, and the increasing quantities used plainly indicate that this is universally recognized."

Borough of Manhattan, New York City, Specifications: It has generally been accepted that the heavy oil called for in these specifications is not a direct distillate, but is formed by the mixing of fluid tar with the creosote oil. This, however, it is not supposed, will detract from its value.

"The oil with which the blocks are treated shall be at least 75% straight coal tar product and shall comply with the following requirements:

1. The specific gravity shall be not less than 1.08 and not more than 1.12 at 38° C (100° F).
2. It shall contain not more than 3% of matter insoluble in hot benzol and chloroform.
3. When subjected to distillation, according to the method hereinafter described, the amount of distillate based on water free oil shall be as follows: Up to 200° C, not more than 1.5%; up to 235° C, not more than 20%; up to 315° C, not less than 20 nor more than 50%. The fraction distilling between 235° and 315° C shall have a gravity of not less than 1.03 at 38° C (100° F)."

Chicago Specifications. A requirement, however, that does call for pure distillates of coal tar can be found in these specifications as given below. It is claimed by some that, while this may be a good oil, it is expensive and can be obtained only in small quantities. It seems, however, to give good satisfaction in the work, and the above, if valid, seem to be the only objections to it.

"It is required by this specification that the oil used shall be wholly a distillate oil obtained only by distillation from coal tar. No other material, of any kind, shall be mixed with it.

"The oil shall contain not more than 1% of matter insoluble in hot benzol and chloroform. Its specific gravity at 25° C (77° F) shall be not less than 1.08 and not more than 1.12.

"The oil shall be subjected to a distilling test as follows: The distillation shall be continuous and uniform, the heat being applied gradually. It shall be at a rate approximating 1 drop per sec, and shall take from 30 to 40 min after the first drop of distillate passes into the receiving vessel. The distillates shall be collected in weighed bottles and all percentages determined by weight in comparison with dry oil. When 100 g of the oil are placed in the retort and subjected to the above test, the amount of distillate shall not exceed the following: Up to 150° C, 2%; up to 210° C, 10%; up to 235° C, 20%; up to 315° C, 40%. The distillation of the oil shall be carried to 355° C. The residue thus obtained when cooled to 15.5° C (60° F) shall not be brittle, but shall be of a soft waxylike nature so that it can be readily indented with the finger. When a small portion of this residue is placed on white filter paper and warmed, the oil spot produced, when viewed by transmitted light, shall appear of an amber color. The tar acids of the distillate from 250° to 315° C must not be less than 6% of this distillate. The amount of the unsaponifiable oil, by sulphuric acid and caustic soda, in the distillate from 250° to 315° C must not exceed 3.5% of this distillate."

Am. Ry. Eng. Assn. Specifications for Grade 1 Oil. "The oil used shall be the best obtainable grade of coal tar creosote; that is, it shall be a pure product obtained from coal-gas tar or coke-oven tar and shall be free from any tar, oil or residue obtained from petroleum or any other source, including coal-gas tar or coke-oven tar; it shall be completely liquid at 38° C (100° F) and shall be free from suspended matter; the specific gravity of the oil at 38° C (100° F) shall be at least 1.03 when distilled by the common method, that is, using an 8-oz retort, asbestos covered, with standard thermometer, bulb ½ in above the surface of the oil; the creosote, calculated on the basis of the dry oil, shall give no distillate below 200° C, not more than 5% below

210° C, not more than 25% below 235° C and the residue above 355° C, if it exceeds 5% in quantity, shall be soft. The oil shall not contain more than 3% water."

The English Report (13) on wood block pavements, to the 3rd International Road Congress, stated that it is of the utmost importance that oil resulting from the distillation of coal tar shall be used, the oils resulting from the making of certain kinds of power gas being absolutely worthless for the preservation of timber. They give the following as the requirements for creosote oil suitable for treating paving blocks:

"The creosote is to be of the description known as heavy oil of tar, obtained solely by the distillation of coal tar, and consists of that portion of the distillate which comes over between 177° and 404° C (350° and 760° F). The specific gravity shall be not less than 1.035 nor more than 1.065 at 15.5° C (60° F), and as nearly as possible 1.05. The liquor must be free from any admixture with any oil or other substance not obtainable from such distillate. It shall contain not less than 20 nor more than 30% of constituents that do not distill over at 315° C (600° F). It must yield not less than 8% of tar acids. The creosoting liquor must become completely fluid when raised to a temperature of 38° C (100° F)."

London Specifications: "The creosote is the oil of tar known as creosote oil, free from all adulteration and impurities, generally free from ammoniacal water and containing not less than 5% of crude coal tar acids. The specific gravity is to range between 1.035 and 1.060 at a temperature of 15.5° C (60° F). It is not to deposit anything when kept at a temperature of 10° C (50° F) for 3 hr."

The Quantity of the Preservative is also a question upon which there is considerable difference of opinion and difference in practice. Like all other engineering questions, what is desired is to know just how much is required so that extra expense will not be incurred by asking for too much. If a pavement is to be subjected to a heavy traffic, where the blocks are liable to wear out before they rot out, it is obvious that a less amount of treatment can be used than if the traffic is to be very light. The early practice was to require a treatment of 20 lb per cu ft; this means a cost of from 50 to 60 cents per sq yd, so that if this amount can be materially reduced there will be a corresponding reduction in the cost of the blocks. Experiments have been made as to the amount required, but it must be remembered that not only present but future requirements must be taken into consideration. Because a 10-lb treatment is satisfactory today it does not follow that it will be in 10 years or longer, but a treatment must be used that will give the greatest economic life to the blocks, and consequently to the pavement. The cost of laying is the same, and if, by an additional 3 or 4 lb of preservative, an appreciable length of life can be given to the pavement, it will often prove to be true economy. It is believed that, as a general proposition, except on heavy traffic streets, a 20-lb treatment is the best. The Am. Soc. Mun. Imp. recommends 18 lb; the Assn. for Standardizing Paving Specifications, 18 lb; the City of Chicago requires about 16 lb per cu ft; the Borough of Manhattan, New York City, 18 lb per cu ft; and the Borough of Brooklyn, New York City, 20 lb per cu ft. In London the general requirement is for 10 lb per cu ft, and in Paris the old practice was 3 lb, but the more recent 10 lb per cu ft.

7. Manufacture of Creosoted Wood Blocks

The planks, if rough, are run thru a surfacer to get uniform thickness, and then sawn into blocks. This is essential in order to get straight courses in the pavement. The blocks are loaded into narrow gauge cage cars, which are charged into long horizontal cylinders which are closed tight. While in the cylinders the blocks are subjected to heat and vacuum treatment,

after which they are completely submerged in oil and subjected to sufficient hydraulic pressure to force a specific amount of preservative into the pores of the wood. The oil is then drained from the cylinder, which is opened, and the cars withdrawn, when the blocks are ready for shipment.

Pine will vary in weight per cubic foot from 40 lb in air-seasoned stock to 50 lb in green lumber. Forty-pound pine is too dry to make a satisfactory street block when treated with oil, whereas 50-lb pine has altogether too much water in it to secure the required penetration. It is therefore necessary to give a live steam treatment to both the light weight wood and the heavy wood to increase the water content of the former and to decrease the water content of the latter. About 2 hr treatment with steam is sufficient to moisten the dry wood, after which a vacuum of about ¾ hr should be applied to draw out as much air as possible from the wood cells. Oil should be run into the cylinder without otherwise breaking the vacuum so that when pressure is applied the wood cells receive oil without very much air in same. In the case of green wood the steam process should be longer than in dry wood, the object being to heat the blocks up to the boiling point of water. When the vacuum is applied a reasonable percentage of the hot moisture in the blocks vaporizes and is sent out of the cylinder along with whatever air escapes from the wood cells. The oil should be run into the cylinder as above. There will be a slight difference between the operation of treatment by various engineers, but it is usually found necessary to apply the pressure gradually in order to secure complete penetration and thoro diffusion. If the preservative used has an excess of free carbon, which makes a messy block, a subsequent bath of live steam while in the cylinder will clean the blocks off very nicely. After the blocks are treated it is desirable that they be shipped to the destination and laid as quickly as possible. Creosoting wood does not prevent entirely the absorption of moisture or the retention of same. It is therefore desirable to treat the blocks with a sufficient quantity of moisture contained in the walls of the cells to insure that the blocks do not shrink and to get them into the street as quickly thereafter as possible, so that they are laid in the pavement before they begin to shrink.

Treatment in a Vertical Tank Plant (20a). "A vertical tank plant for creosoting wood paving blocks has recently been installed at Terre Haute, Ind., by the Chicago Creosoting Co. These vertical retorts or tanks allow of material saving in the handling of material and present other advantages worth being noted by those interested in wood block paving. Briefly, these retorts are charged by disc conveyors, which carry the blocks direct from the block saw to the opened inlet head at the top of the retort being filled. One retort is filled while the other is engaged in impregnating its charge of blocks. When the blocks are to be taken out of a retort the outlet head is opened and the blocks flow directly into the cars to be loaded. The saving of labor and time by means of the loading and unloading equipment used for these retorts is the principal advantage gained in the operation of the new plant. A notable record for loading a car with creosoted blocks was recently made at this plant, when a 40-ft gondola railroad car was loaded in 2 min 5 sec with sufficient 3½-in blocks to lay 370 sq yd of pavement. This is at the rate of 2 solid cu yd of blocks per min. When horizontal retorts are used for treating paving blocks, the blocks are loaded into narrow-gauge tram cars at the saw. These cars are filled one at a time, until enough cars are loaded to make the desired length of train which is then switched into one of the horizontal retorts. After treatment the cars must be switched out of the retort, and dumped one at a time by a locomotive crane or other device into railroad cars. The vertical retort system eliminates all the narrow-gauge tracks and cars, the small locomotive, if one is used for switching the cars, the locomotive crane or other dumping device and all manual labor necessary for paving the blocks in the tram cars and for switching and unloading the cars. Another important advantage obtained with the use of the vertical

retorts is that such a retort furnishes a method of determining the exact volume of blocks being treated and the exact amount of oil absorbed by the blocks at each application. The manner in which these amounts are determined is explained in connection with a description of the creosoting process used at this plant."

The Bethell Method of Creosoting Timber is described by Weiss (7) as follows: "This process is named after John Bethell who took out patents in England in 1838. It is commonly referred to in our country as the full-cell process. Either green or seasoned timber can be treated by this process, creosote oil, dead oil of coal tar, being the preservative used. The timber to be treated is loaded upon steel cars or buggies, which are run into horizontal steel cylinders usually 7 ft in diameter by 132 ft long. Their length, however, varies from about 50 to 180 ft and diameter from 6 to 9 ft. If the timber is green, it is subjected to a bath of live steam for several hours, after which a vacuum is drawn by means of pumps. This also is held for one or more hours according to the judgment of the operator. If the timber is air seasoned, the steam bath is generally omitted. Creosote oil is then run or pumped into the cylinder and a pressure of 100 to 180 lb applied until the gauges show the desired amount of oil has been forced into the wood. The excess oil is then drained from the treating cylinder and the timber is allowed to drip for a short period, after which the process is ended and the charge is removed. Many treating engineers draw a vacuum in the cylinder after the excess oil has drained from it, as this tends to hasten the drip and dry the timber. The Bethell or full-cell process is considered the standard process of treating timber with creosote, and the most effective results in prolonging the life of wood have been secured by it. On account of the relatively large amount of oil which the ties absorb, the process is, however, the most expensive and for this reason several modifications have been made."

Treatments with Sulphate of Copper and Corrosive Sublimate. A firm in Portland, Me., treats blocks with this latter material. This consists in steeping the timber in a solution of bichloride of mercury by the open tank cold bath method. These blocks are used to quite an extent on bridges, as they are extremely light, the treatment adding very little to the weight of the blocks. In Brussels in 1913 blocks were treated with sulphate of copper, but to so slight an extent that it seemed doubtful if the treatment could add very much to the life of the block.

Municipal Plant at Paris. The process of paving with wood in Paris is carried on in a different way from that of any other city in Europe, as the blocks are manufactured and furnished by the municipality to the contractor. The city has a very large and efficient plant, in a central location. The timber is unloaded from the cars directly to piles by means of an electric tiering machine. These piles are approximately 40 ft high, most of them kept under glass roofs. The blocks are sawed by an electrically driven machine, which cuts 16 blocks at once, the sticks being fed automatically to the saws and the blocks automatically discharged, with the grain up, to the inspection table. From the table, previous to 1913, they were loaded into very small iron treating cars, five or six of which were run under the creosote oil tank, where each car was filled by gravity with an oil at 80° C (176° F). After 20 min the oil was drawn off from the bottom of the cars and the blocks taken to the storage yard. The average absorption was 3 lb per cu ft, and naturally the penetration was very slight. It is not surprising that the blocks decayed before wearing out, but at first sight it is very surprising that they did not continually buckle and bulge. In 1913 a plant was installed in Paris which would treat the blocks in practically the same way as are those of London, the idea being to impregnate the blocks with 10 lb of oil per cu ft, not so much to increase the life of the blocks as to prevent bulging. The oil used had a specific gravity of 1.08. One of the engineers in Paris, in speaking of the bulging of wood pavements, said it was bound to occur and that the only thing to do was to take the pavement up and relay it. If, however, a more thoro treatment is given to the blocks, as would be the case if the plans of 1913 were carried out, the bulging would undoubtedly be materially less. The material of the blocks in Paris is such that, as the blocks wear, they batter down, with rough edges, so that when they are taken up from the heavy traffic streets they have these edges trimmed with a specially designed machine, after which the blocks are relaid on lighter traffic streets. Sometimes the surface of the block is so rough that it is necessary to saw off the entire top. This is done upon the street if the blocks are to be immediately used. During 1911 over 3 000 000 blocks were treated in this way. In 1911 the municipal plant manufactured

20 378 000 blocks, of which 313 000 were creosoted under pressure. The total number of blocks made would lay about 465 000 sq yd of pavement.

Chicago Specifications: "The blocks shall be placed in an air-tight cylinder where, by means of steam and the vacuum pump, the sap in the blocks will be vaporized and the moisture in them removed. During the process of steaming a vent shall be kept open in the cylinder to permit the escape of water, air and condensed steam in the cylinder. After the heating or steaming period, the drain or vent in the bottom of the cylinder shall be opened and all moisture removed from the cylinder. During the vacuum period the temperature in the cylinder must be above the boiling point of water under existing vacuum. When the cylinder is thoroly drained, a vacuum of not less than 20 in shall be maintained. When the blocks are thoroly dry the cylinder shall be filled with oil destroying a vacuum of not less than 20 in and pressure shall then be applied and increased gradually to not more than 200 lb per sq in and maintained until 16 lb of oil have been forced into and retained in each cubic foot of timber and until the oil has impregnated the blocks to the satisfaction of the Board of Local Improvements. The pressure period on the oil shall be continuous and of a duration of not less than 3 hr. After the surrounding oil has been removed, the blocks shall remain in the closed cylinder for a period of 30 min to allow the excess oil on the surface of the blocks to drain off. The oil thus drained off shall be forced back into the treating tank in order to determine the amount of impregnation. In the process of treating the blocks, a correction must be made for any water contained in the cylinder. Compensation shall also be made for leaks and other wastes of oil that may occur during treatment. If, in the treatment of the blocks, more oil is injected per cubic foot of timber than is called for in the specifications, such excess oil must not be removed. The temperature of the oil after entering the cylinder shall be not lower than 74° C (165° F). The cylinder shall be provided with sufficient steam coils to fully maintain this temperature thruout injection. The oil tanks and cylinder in which the blocks are treated shall be equipped with the necessary gauges, thermometers and draw-cocks in order to facilitate a thoro inspection of the materials and treatments. The cylinder shall be equipped with the proper connections and apparatus for artificially seasoning timber before the impregnation with the creosote oil. The plant shall be provided with proper means for obtaining the absolute measurement and weight of all oils entering the cylinder and the amount of oil absorbed by the blocks."

Kansas City, Kan., Specifications: "The method of treatment must be thoro and up-to-date, containing the necessary air-tight cylinders, steam pipe, boilers, vacuum and force pumps, tanks, gauges, etc, and shall be carried on in accordance with the best modern practice under the joint supervision of the manager of the plant and the city engineer or his representative. During the process of treatment, the blocks shall be subjected to a thoro steaming of from 1 to 4 hr, as required by the city engineer, and then to a vacuum of from 22 to 26 in of mercury, during which time the temperature in the cylinder shall be at all times above the boiling point of water under the existing vacuum. After the moisture and sap extracted by the steaming and vacuum have been drained from the cylinder, the vacuum shall be destroyed by the admission of the creosote oil to completely fill the cylinder, and not by the admission of air. Pressure of from 100 to 200 lb per sq in shall then be applied and maintained until 16 lb for traffic streets and 18 lb for residence streets of the creosote oil have been forced into and retained in each cubic foot of timber. The pressure shall be gradually applied, and if in the opinion of the city engineer better results can be obtained, the maximum allowable pressure may be fixed at any point less than 200 but more than 100 lb per sq in, and maintained at that figure long enough for the wood to absorb the specified amount of oil. The temperature of the oil after entering the cylinder shall at no time be less than 66° C (150° F) or more than 116° C (240° F). The blocks, after treatment, shall show a satisfactory penetration of oil thruout. All blocks which are in any way defective or which have been badly warped or checked in the process of treatment shall be rejected. Before removing the charge from the cylinder, the blocks shall be given a steam bath lasting at least ½ hr to clean off all the surplus oil. The manufacturer shall furnish all appliances necessary for tests and all labor which may reasonably be required in removing material for examination. The oil tanks and treating cylinders shall be provided with necessary gauges, thermometers, draw-off cocks, etc, affording adequate means for determining the absolute weight of oil retained in

the blocks. The contractor shall furnish a copy of the plant record showing a complete statement of each operation in the creosoting process."

London Specifications: "The blocks are to be creosoted, the temperature of the oil being not less than 66° C (150° F), the creosote to be forced into the blocks at a pressure of not less than 80 lb to the sq in, and to the extent of 10 lb of oil to the cu ft of timber. Before applying the pressure the cylinder is to be exhausted to a vacuum equivalent to 20 in of mercury."

English Practice. The report (13) to the 3rd International Road Congress of English engineers states that the best known process for creosoting timber is BOULTON'S. While it is claimed that wet timber can be successfully creosoted by this process, it is preferred that the timber should be seasoned in the blocks for at least 6 months before being cut up into the sizes of the blocks for pavement. The treatment is described as follows: "The blocks are placed in closed iron cylinders to which a steam dome is fitted, and a condenser is also fitted to the air pump. The pump is started, and a vacuum of 10 to 15 lb per sq in is obtained, and oil at a temperature of 100° C (212° F) is then forced into the cylinder at a pressure of from 50 to 60 lb. The creosote oil at this temperature forces the air and moisture out of the timber in the form of steam, and the air pump withdraws this air and steam from the dome."

The following requirement for treatment is given by WOOD (9): "The creosote to be forced under pressure into the blocks until they have absorbed an amount of 10 lb to each cu ft, and in such a manner that any block split open will show the creosote to have penetrated right thru. The creosote is to be a liquid heavy oil of tar, commonly called creosote, and is to contain not less than 8% of tar acid. It will be subjected to analysis, and the contractor is only to use such as may be approved by the analyst."

Treatment in Berlin. The wood blocks are immersed in a bath of carbolized coal tar, at room temperature, and allowed to remain 15 or 20 min. This process is said to give good satisfaction.

Inspection at Plant. Before the blocks are put into the cylinder, the inspector should select a few average blocks from each cage and measure out from the same exactly 1 cu ft. This is easily done by laying the blocks in a single row, end to end, until the requisite length is covered, the last block being cut to exact length with a hatchet. For instance, blocks 4 in deep by 4 in wide will take 9 in in length for 1 cu ft. This average cubic foot should be weighed, placed in a wire basket, and subjected to the same treatment in the cylinder as the rest of the charge. When the cylinder door is opened, this cubic foot should be taken out and weighed to determine whether the charge as a whole has received the requisite amount of oil per cubic foot. If the weight is all right, the blocks should be split with a cleaver to see whether the penetration and the diffusion are satisfactory. It is possible to get 20 lb of oil per cu ft in blocks by very quick treatment, where the penetration and the diffusion will show bad, whereas 10 lb per cu ft by more careful impregnation may show good penetration and diffusion. The results obtained by the cubic foot test as outlined above should always be taken in connection with the total quantity of oil used, as shown by the tank readings, and the two should correspond very closely.

Test for Water and Oil Content. Claims are sometimes made by creosoting companies as to the amount of moisture removed in the cylinder by the high vacuum treatment and allowances asked for, which may or may not be legitimate. Ordinarily the inspector can determine this matter for himself and prove beyond any question exactly what the preliminary treatment has done. This method is little known, but should be used from time to time as a check on the operation. The test is made as follows:

Two cubic feet are selected from the untreated blocks as an average; it is easy to pick out samples so that each cubic foot is made up of sister blocks. Both cubic feet are weighed, and will ordinarily show the same weight per cubic foot. One cubic foot

is put into the cylinder as outlined above; the other cubic foot is taken to a wood drilling machine and a large number of borings made quickly. These borings are thoroly mixed and 100 g of the borings are carefully weighed and thrown into a copper distilling apparatus with a sufficient quantity of xylo to thoroly submerge same. The xylo and borings are then boiled in the apparatus, and all the water in the wood distills over and separates at the bottom of the receiving test tube, which should be graduated in cubic centimeters. The whole test may be made in 20 min. The number of cubic centimeters of water then in the test tube is the percentage of water contained in the untreated blocks. From this the dry weight per cubic foot of the untreated blocks is determined. After the charge is treated, the treated test cubic foot is bored in the same manner as the untreated one, and the percentage of water in the treated blocks determined in the same manner. Thus the inspector knows the weight of 1 cu ft of treated block, the weight of the dry wood, the weight of the water in the blocks, and, by the difference, gets the exact weight of the oil in the same.

Defects in Wood. Wood block plants receive lumber in the shape of planks. These planks should be sorted at the works; first, to permit lumber of approximately the same weight per cubic foot to be treated by itself; and, secondly, to throw out culls or rejects. The usual defects are: poor manufacture, the planks being too thin or having a tapered surface; split planks, wind shakes, loose and rotten knots, wane, large worm holes, and red heart. Red heart may not always be detected in the plank before it is sawn; the inspector, therefore, should particularly look over the cut blocks, as red heart shows very plainly in first cut lumber. Red heart is probably the most important defect to be caught by the inspector at the works, as most of the other defects can be discovered before the blocks get into the pavement.

8. Specifications for Wood Blocks

The following specifications were adopted in 1916 by the Am. Soc. Mun. Imp. For sections covering the construction of the pavement, see Art. 10. Specifications relative to the practice in several American and European cities pertaining to physical properties of wood blocks will be found in Art. 4; to size of blocks in Art. 5; to preservatives in Art. 6; and on manu facture of wood blocks in Art. 7.

"**Timber.** The wood from which the blocks are to be manufactured shall be southern yellow pine, Douglas fir, tamarack, Norway pine, hemlock or black gum. Only one kind of wood shall be used in any one contract. The blocks must be sound and must be well manufactured, square butted, square edged, free from unsound, loose, or hollow knots, knot holes and other defects such as shakes, checks, etc, that would be detrimental to the blocks. The number of annual rings in the 1 in which begins 2 in from the pith of the block shall not be less than six, measured radially, provided, however, that blocks containing between five and six rings in this inch shall be accepted if they contain 33.3% or more summerwood. In case the block does not contain the pith, the 1 in to be used shall begin 1 in away from the ring which is nearest to the heart of the block. The blocks in each charge shall contain an average of at least 70% of heartwood. No one block shall be accepted that contains less than 50% of heartwood.

"**Size of Blocks.** The blocks shall be from 5 to 10 in long, but should preferably average two times the depth; they shall be * in in depth. They may be from 3 to 4 in in width but in any one city block all of them shall be of uniform width. A variation of 1/16 in shall be allowed in the depth, and 1/8 in in the width of the blocks from that specified. In all cases the width shall be greater or less than the depth by at least 1/4 in.

*The Committee recommends blocks 4 in in depth for very heavy traffic streets; blocks 3½ in in depth for moderate traffic streets. For light traffic streets blocks 3 in in depth may be used, but where 3-in blocks are used no block shall be longer than 8 in.

"**Preservative.** The preservative to be used may be either a coal tar paving oil or a coal tar distillate oil as herein specified.

"COAL TAR PAVING OIL. The oil shall be a coal tar product of which at least 65% shall be a distillate of coal-gas tar or coke-oven tar, and the remainder shall be refined or filtered coal-gas tar or coke-oven tar. It shall comply with the following requirements:

1. It shall not contain more than 3% of water.
2. It shall not contain more than 3% matter insoluble in benzol.
3. The specific gravity of the oil at 38° C (100° F) shall not be less than 1.07 nor more than 1.12.
4. The distillates based on water free oil shall be within the following limits: Up to 210° C, not more than 5%; up to 235° C not more than 25%. The residue above 355° C, if it exceeds 35%, shall have a float test of not more than 80 sec at 70° C (158° F).
5. The specific gravity of the fraction between 235° and 315° C shall not be less than 1.02 at 38°/15.5° C (100°/60° F). The specific gravity of the fraction between 315° and 355° C shall not be less than 1.09 at 38°/15.5° C (100°/60° F).
6. The oil shall not yield more than 10% coke residue.

"COAL TAR DISTILLATE OIL. The oil shall be a distillate of coal-gas tar or coke-oven tar, and shall comply with the following requirements:

1. It shall not contain more than 5% of water.
2. It shall not contain more than 0.5% of matter insoluble in benzol.
3. The specific gravity of the oil at 38° C (100° F) shall not be less than 1.06.
4. The distillates based on water free oil shall be within the following limits: Up to 210° C, not more than 5%; up to 235° C, not more than 15%. The residue above 355° C, if it exceeds 10%, shall have a float test of not more than 50 sec at 70° C (158° F).
5. The specific gravity of the fraction between 235° and 315° C shall not be less than 1.02 at 38°/15.5° C (100°/60° F). The specific gravity of the fraction between 315° and 355° C shall not be less than 1.09 at 38°/15.5° C (100°/60° F).
6. The oil shall yield not more than 2% of coke residue.

"WATER-GAS TAR.* The preservative shall be refined water-gas tar and shall comply with the following requirements:

1. The specific gravity shall be not less than 1.12 nor more than 1.14 at 38° C (100° F), referred to water at the same temperature.
2. Not more than 2% shall be insoluble by hot extraction with benzol and chloroform.
3. On distillation, which shall be made as hereinafter described, the distillate based upon water free oil shall be within the following limits:

   Up to 210° C, not more than 5%
   Up to 235° C, not more than 15%
   Up to 315° C, not more than 40%
   Up to 355° C, not less than 25%
4. The specific gravity of the total distillate below 355° C shall not be less than 1.00 at 38° C (100° F), referred to water at the same temperature.
5. The oil shall not contain more than 2% water, and due allowance shall be made for all water and insoluble foreign matter it may contain, by injecting a corresponding additional quantity into the blocks.

"**Treatment.** The timber may be either air seasoned or green, but should preferably be treated within 3 months from the time it is sawed. Green timber and seasoned timber shall not, however, be treated together in the same charge. The blocks shall be treated in an air-tight cylinder with the preservative heretofore specified. In all cases, whether thoroly air seasoned or green, they shall first be subjected to live steam at a temperature between 104° and 116° C (220° and 240° F), for not less than 2 hr

---

*In view of the fact that some cities are using a water-gas tar, your Committee deems it advisable to suggest a specification for their guidance. This specification is the one submitted and agreed to by C. N. Forrest, Chemist of the Barber Asphalt Paving Co., and W. H. Fulweiler, Chemist of the United Gas Improvement Co.

nor more than 4 hr, after which they shall be subjected to a vacuum of not less than 22 in, held for at least 1 hr. While the vacuum is still on, the preservative oil, heated to a temperature of between 82° and 104° C (180° and 220° F), shall be run in until the cylinder is completely filled, care being taken that no air is admitted. Pressure shall then be gradually applied not to exceed 50 lb at the end of the first hr, nor 100 lb at the end of the second hr and then maintained at not less than 100 lb nor more than 150 lb until the wood has absorbed the required amount of oil.*

"After this a supplemental vacuum shall be applied, in which the maximum intensity reached shall be at least 20 in and shall continue for a period of not less than 30 min. If desired, this vacuum may be followed by a short steaming period. In any charge the blocks shall contain at least 16 lb of water free oil per cu ft of wood at the completion of the treatment. The blocks after treatment shall show satisfactory penetration of the preservative, and in all cases the preservative must be diffused thruout the sapwood. To determine this, at least 25 blocks shall be selected from various parts of each charge and sawed in half at right angle to the fibers thru the center, and if more than one of these blocks show untreated sapwood the charge shall be retreated. After retreating, the charge shall again be subjected to a similar inspection. The surface of the blocks after treatment shall be free from deposit of objectionable substances, and all blocks that have been materially warped, checked or otherwise injured in the process of treatment shall be rejected.

"Method of Sampling Preservative. CONTINUOUS DRIP SAMPLE. When the oil is being loaded or discharged by means of a pump, the following methods shall be used: The pipe lines thru which the material is being pumped shall be tapped on the discharge side of the pump, preferably in a rising section of the pipe line. The sample shall be taken by means of a ½-in pipe, extending half way to the center of the main pipe, and the inlet of the ½-in pipe shall be turned to face the flow of the liquid. This pipe shall discharge into a barrel or drum of 50 to 100 gal capacity, and the plug cock regulated so as to secure a continuous, uniform stream during the entire pumping of the shipment. The barrel, or preferably the iron drum, should be provided with a small steam coil sufficient to keep the contents thoroly liquid. The temperature shall not exceed 49° C (120° F). The contents of the barrel or drum shall be very thoroly agitated, and small samples for testing taken immediately. The amount of the drip sample collected shall be not less than 1 to 1000 gal of material handled, excepting in the case of large boat shipments, where a maximum of 100 gal will suffice.

"STORAGE TANK SAMPLES. In sampling from storage it is necessary to secure samples from different levels, and where possible this may be done by means of small outlet cocks, at regular intervals, from the top to the bottom of the storage tank. In such cases about 1 gal of tar or oil shall be drawn from each outlet cock and thoroly mixed and a portion taken for testing. The stream from each cock shall be always allowed to flow for sufficient length of time to enter the outlet pipe and nipple, before commencing to collect the sample. When tanks have no outlet cocks, a vessel having a string attached to the cork may be lowered to measured depth, representing a number of different levels in the tank, and the cork removed when the vessel has reached the proper level. These samples shall be combined for an average as above.

"Handling Blocks After Treatment. Blocks shall preferably be laid in the street as soon as possible after being treated. If they can not be laid within 2 days, provision shall be made to prevent them from drying out by stacking in close piles and covering them, and, if possible, sprinkling them thoroly at intervals. The blocks shall be well sprinkled, under the direction of the purchaser, about 2 days before being laid.

"Inspection. All material herein specified and processes used in the manufacture of the blocks therefor shall be subject to inspection, acceptance or rejection at the plant of the manufacturer, which shall be equipped with all the necessary gauges, appliances and facilities to enable the inspector to satisfy himself that the requirements of the specifications are fulfilled. The purchaser shall have the further right to inspect the blocks after delivery upon the street, for the purpose of rejecting any blocks that do not meet these specifications, except that the plant inspection shall be final with respect to oil and treatment."

---

*This treatment is recommended for yellow pine only. It is probably also suited to Norway pine, hemlock, black gum and tamarack, but not Douglas fir. Further recommendations on the treatment of these species are reserved for the future.

CONSTRUCTION

9. Laying the Pavement

The Foundation for a wood block pavement should be of Portland cement-concrete, mixed in standard proportions. The surface of the concrete should be somewhat smoother than for granite, as it is more important that the wood blocks should be well bedded than should stone blocks, as they will break more easily. In America the practice is to lay a cushion of either sand or mortar upon the surface of the concrete before laying the blocks, so that they will become well bedded. Most cities specify either a sand or a mortar bed cushion, reserving the right of course to specify whichever one is desired for any particular street.

Cement Mortar Bed. It is believed that the mortar bed is the better, because, after the pavement is once laid, it should be in such condition that the individual blocks will not settle. If blocks are laid on a sand cushion, the pavement is rolled or rammed, as the sand must be of slightly varying depths; the blocks will get an uneven pressure under the roller or rammer, and so, under traffic, where the wheels strike the individual blocks, depressions are liable to occur, making the pavement slightly undulating. This is undesirable and should be avoided if possible. If a mortar bed is used the blocks are thoroly imbedded in it by the action of the roller or rammer, and, tho used dry, it soon sets, and the blocks become firmly fixed on a hard base. The cushion is practically impervious to water, so that the cushion can never be washed away by water getting under the blocks, as sometimes happens with the sand cushion. When a sand cushion is used it is generally 1 in thick, and the mortar bed is generally made ½ in thick, mixed in the proportion of 1 : 1 or 1 : 2, according to the ideas of the engineer. The general practice in the United States seems to be to use the mortar bed. If this is used, after it sets, the pavement becomes as solid as if it had all been laid at one time.

In Europe, however, the practice is different in all cities using wood block pavement to any extent. There the concrete is either so laid that it will have an absolutely smooth surface, or it has an upper layer, perhaps ½ in in thickness, formed of finer materials, so that the surface is easily made smooth. The concrete is laid with a straight-edge, so that it is absolutely true to the desired crown, and trowelled in such a way that the surface is as smooth as the ordinary cement walk. In some instances blocks are laid directly upon the concrete and in others upon a thin coating of pitch, which is first spread upon the concrete surface. A small amount of pavement, laid on the concrete with and without this pitch coating, was put down in Chicago in the latter part of 1914. It has, however, not been in use long enough to demonstrate its action. The wood pavements of Europe are as a rule softer than those of America, so that they would naturally be more resilient, but even the hard woods of Australia are laid directly upon the concrete base.

Petrograd. The wood pavements of this city are undoubtedly in a class by themselves. The timber used is generally pine, altho spruce is used to a certain extent. The blocks are manufactured by hand and by machinery, the hand-made blocks costing about 84 cents per sq yd and the machine-made about 63 cents per sq yd, according to the amount manufactured each year. It is stated, however, that, as there is no competition in the manufacture of machine-made blocks, the price of them is kept the same as that of hand-made blocks. In the construction of the pavement the blocks are laid on concrete and on wood. A 1 : 4 : 6 broken stone concrete is laid about 6 in deep and covered with a layer of 1 : 1 cement mortar about 1 in thick. The blocks are laid closely together. The wooden foundation consists, first, of pine logs 9 in in diameter laid across the street a distance of about 39 in apart. On top of the logs is laid a flooring of planks 2.4 in thick and from 7 to 8 in wide. These planks are fastened to the logs by iron nails. The planks are generally laid with an

open joint so that the water can pass thru them to the soil beneath, where drains are constructed connecting with the nearest reservoir. The pavement when completed is covered with two coats of coal tar or rosin, after which a thin layer of sharp, coarse sand is thrown over it. Occasionally the lower parts of the blocks are dipped in tar before being laid. The cost of the pavement as above constructed is $0.99 per sq yd for the pavement proper; with concrete foundation, $2.45 per sq yd, and with the wooden foundation, $1.77 per sq yd. Figs. 1 and 2 show construction on wooden foundation in Petrograd.

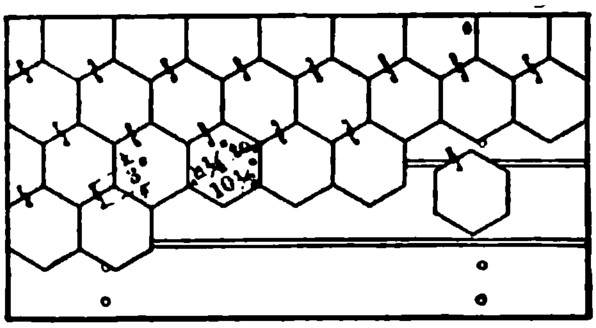

Fig. 1

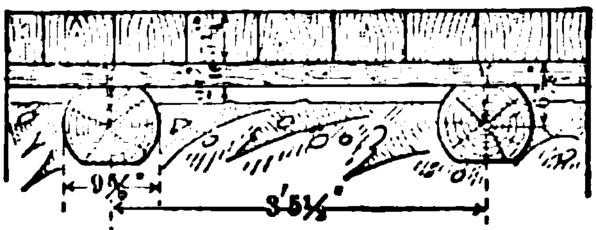

Fig. 2

Vroublensky (45) says: "The wood blocks are soon crushed and ground down and absorb liquid filth, diffusing a bad smell and possibly serving to spread infectious diseases. Also in the interstices between the blocks dirt collects. With wooden foundations, the pavement seems to be still more incomplete in the sanitary sense, as the dirt percolating thru it soaks into the ground, dirtying and infecting it. Finally, organic dust is formed by the wear of the pavement, which, rising during the dry time of the year, infects the air and makes it injurious to health. It is evident that the methods employed in Petrograd cannot be recommended."

Laying the Blocks. The fundamentals of the best American practice are described in the 1916 specifications of the Am. Soc. Mun. Imp. (see Art. 10).

Borough of Manhattan, New York City, Specifications provide for practically the same procedure as those of the Am. Soc. Mun. Imp., except that they do not call for a row of blocks to be laid parallel to the curb; they provide that joints shall be broken by a lap of not less than 2½ in, and they do not require any expansion joint. Where car tracks exist on the street they provide that the spaces between the web of the rail and the blocks and directly under the head of the rail shall be filled with a stiff mortar composed of one part of Portland cement and three parts of clean, sharp sand; the mortar to be carefully struck so that it will not project beyond the vertical plane of the edge of the rail head, and to be kept in position until the pavement is laid.

Chicago Specifications require that: "The blocks shall be laid in parallel courses across the roadway at an angle of approximately . . . . degrees from the center line thereof, except at the intersections of all alleys, where they shall be laid at right angles with the center lines thereof. On intersections and junctions of lateral streets, the blocks shall be laid at an angle of 45° with the line of the street, unless otherwise ordered by the Engineer. The blocks shall be laid with the fiber of the wood running in the direction of the depth. Gutters shall be constructed as directed by the Engineer. The courses shall break joints alternately by a lap of not less than 2 in and the blocks shall be driven together except where joints for expansion are constructed. The blocks, when set, shall be rolled with a steam roller weighing not less than 5 tons, until firmly bedded and brought to a uniformly even surface. After rolling, all imperfect blocks shall be removed and replaced by perfect blocks. Broken blocks shall not be used except to break joints in starting courses and in making closures. If the blocks that have been laid should become wet before the filler is applied, they must be taken up and reset at the contractor's expense, if the Engineer so directs. In no case will teams be allowed on the work before the wearing surface is completed."

The Brooklyn, N. Y., Specifications provide that: "The joints between the blocks shall be not more than ¼ in in width when bituminous filler is used, and not more than ⅛ in in width when sand filler is used. The blocks shall be laid by the pavers standing upon the blocks already laid, and not upon the bed of mortar. The blocks shall be laid in straight courses, at right angles with the line of the street, except at street intersections, where they will be laid diagonally, as the Engineer may direct. All longitudinal joints shall be broken by a lap of not less than 3 in."

Provisions for Expansion. When the creo-resinate wood blocks were

first laid in Brooklyn no provision was made for an expansion joint, it being thought that if the blocks were so treated that they would not absorb more than 3% of water, when dried for 24 hr at a temperature of 38° C (100° F) and then immersed in water for 24 hr, there would not be sufficient expansion to do any harm. This was found to work out in practice, and no material amount of bulging or swelling occurred in the pavements so laid. When, however, the rosin was dropped from the preservative and an oil used, it was deemed best in most cities to provide for an expansion joint, altho this procedure has not been followed in the Borough of Manhattan, New York City. Most engineers think that it is not possible, and perhaps not desirable, to treat a block so as to make it absolutely waterproof, and if a block can be so treated as to prevent decay and at the same time not have too much expansion, it may be better to lower the amount of treatment in the blocks and so reduce expense. It must be remembered, however, that in order to expand from side to side across the street to any appreciable extent the blocks must move on the base, which is undesirable, if not impossible if the blocks are imbedded in a mortar cushion. The general practice in America, however, is to provide for an expansion joint lengthwise of the curb and fill the same with some bituminous material. In some instances joints have been laid crosswise of the pavement. This, however, is not the general practice, and, unless absolutely necessary, is not desirable, as it gives a wide joint, and therefore causes undue wear.

In Europe, the practice is always to provide an expansion joint near the curb. This is more necessary there than in America, as the blocks do not have a heavy treatment. On one street where wood block was being laid in London in 1913, two rows of the blocks were being laid parallel to the curb, with two expansion joints about 1 in wide, one adjacent to the curb and the other between the rows of blocks, these being filled with clay or some other similar material. Such filling for expansion joints is more common in Europe than the use of bituminous material. In Paris the expansion joint is sometimes filled with an oblong hollow device made of thin sheet steel, about 3 in high and 1¼ in wide; this is placed in the joint, and is supposed to be elastic enough to give under the pressure of the expanding blocks and so prevent bulging.

The Specifications of the Borough of Brooklyn, New York City, provide that when bituminous joints are specified, the joints are to be immediately filled with a hot filler, but with sand joints the pavement is to be rolled. Before the blocks are laid, it is specified that a board 5 in in width, 1 in thick at top and ¾ in thick at the bottom, shall be placed along and against the curb, the blocks at the beginning and the end of each course to be set against these boards. After the blocks are rolled, the boards are withdrawn, and the spaces between the blocks and the curb filled with a bituminous filler. A joint ½ in in width shall be left along the rails of the trolley tracks, and this joint shall also be filled with a bituminous filler. It is also specified that after the joints have been completely filled and the pavement rolled a layer of sand shall be spread over the surface and allowed to remain there for 10 days. It is also provided that if at any time during the maintenance period the street should require sand for the purpose of absorbing surplus oil or joint filler, it shall be supplied by the contractor.

The Chicago Specifications provide that on each side of the roadway a longitudinal joint shall be formed by placing a 1½-in board on edge against the curb. The blocks shall be firmly bedded against said boards. The boards shall remain in place until the blocks are rolled, and immediately preceding the application of the filler they shall be carefully removed without disturbing the adjacent blocks.

As an instance of a special case of laying blocks, when the Strand, in London, was paved with wood, in about 1901, it was desired to have the work done with as little disturbance to traffic as possible. The portion paved was from Trafalgar Square to Charing Cross, some 1200 or 1300 ft. The work was done from curb to curb,

proceeding without stopping day and night, and, as was stated by the Engineer, the blocks were laid upon the concrete when it was so soft that the pavers had to have planks to stand on so as not to deform the concrete. The entire work was completed in 3 days. Before being thrown open to traffic it was covered with about 2 in of coarse gravel. The Engineer also stated that, while he had some misgivings about how the work would turn out, it was satisfactory in every respect. In 1914, when this street was repaved, one-half of the street only was done at one time.

Joint Filling. Sand. The question of filling joints in wood pavement has received as much discussion as that for stone block pavement, and the materials used are practically the same. The creo-resinate pavements laid in Brooklyn, N. Y., had all the joints filled with sand, and after a little traffic they were completely filled, and undoubtedly as nearly waterproof as if a bituminous or cement grout filler had been used. It can be said, too, of a sand filler, that if the blocks bleed, the sand in the joints will absorb a certain amount of the oil; on the other hand, when the sand is closely packed it cannot be compressed, and therefore will not take up any expansion of the blocks. Where the traffic is quite heavy it is believed that a sand joint filler is as good as any other, if not better.

Cement Grout. This filler has been used to a certain extent, but it does not seem to have much to commend it. The mortar cannot adhere to any extent to the wood, as it can to stone, and the film of cement, after it has set, must be very thin and liable to break under traffic, so that the filler will be little better than sand. It, too, requires that the street shall be closed for a sufficient length of time to allow the mortar to thoroly set; otherwise the result before spoken of will ensue.

Bituminous Filler. A bituminous filler is probably used more generally in wood pavements than any other kind. It has one great merit in that every joint between the blocks is really an expansion joint so that it will take up a certain amount of the expansion in the blocks and thus have a tendency to prevent bulging. That it will not entirely do this is evident from experience. But it adds to the trouble if the blocks bleed to any extent, as, if the bleeding is caused by expansion, the surplus that is used for the filler is crowded to the surface, adding materially to the amount that exudes from the blocks themselves.

The general practice in Europe is to fill the joints with some bituminous material, but cement grout is used to a certain extent, and sometimes a combination of both, the lower part of the joint being filled with bituminous material and the upper part with cement to prevent any liability of trouble from stickiness.

10. Specifications for Construction

The following specifications were adopted in 1916 by the Am. Soc. Mun. Imp. For sections covering physical properties of wood blocks and preservatives, and method of manufacture, see Art. 8. Specifications relative to the practice in several American and European cities pertaining to details of construction will be found in Art. 9.

"**The Foundation** for the pavement shall be of cement-concrete made in accordance with the specifications for concrete paving foundations and shall be * inches in thickness. At no place shall the surface of the finished concrete vary more than ½ in from the given grade.

"**Cushion.** Bituminous. Over the concrete foundation laid as specified above shall be spread a layer of cement mortar composed of one part Portland cement to two parts of sand. This mortar shall be of such a consistency that it may be easily spread,

*The Committee recommends that the concrete base be at least 5 in in thickness and under heavy traffic 8 to 9 in is recommended.

and must be applied to the surface of the concrete not more than 45 min after the placing of the concrete foundation. This mortar must be struck by templets to a surface parallel to the grade and contour of the finished pavement in such a manner that when the blocks are set the surface of the pavement shall conform accurately to the established grade. After this mortar coating is thoroly set and hardened, it shall be painted with a coal tar pitch as specified under bituminous filler, or other suitable waterproofing paint. The paint coat must be applied as thin and as smoothly as possible, and at no place shall it be over ⅛ in in depth. The blocks shall be laid as specified below directly on this paint coat within at least 30 min after it has been applied.

"MORTAR BED. The concrete foundation prepared as specified above shall be cleaned and swept and shall be thoroly dampened immediately in advance of the spreading of the cushion course. Upon the surface of the foundation thus prepared shall be spread a layer of mortar not exceeding ½ in in thickness and made of one part Portland cement of the character specified for use in the foundation and three parts of sand. Only sufficient water shall be added to this mixture to insure a proper setting of the cement, the intention being to produce a granular mixture which may be raked or struck by templets to the desired grade. The mortar shall be thoroly mixed and shall be spread in place upon the foundation by means of templates immediately in advance of the laying of the blocks to such a thickness that when the blocks are set and properly bedded in the mortar, their tops shall conform accurately to the finished grade of the roadway.

"SAND. Upon the concrete foundation shall be spread a cushion of sand 1 in in thickness. The sand cushion shall be struck by templates to a surface parallel to the grade and contour of the finished pavement in such a manner that when the blocks are set and thoroly bedded in the sand the tops shall conform accurately to the finished grade of the pavement. The sand used in this cushion shall all pass the ¼-in screen and must contain between 10 and 25% of loam or clay.

"Laying the Blocks. Upon the bed thus prepared the blocks shall be carefully set with the fiber of the wood vertical, in straight parallel courses, leaving a space next to the curb 1 in in width for the expansion joint. They shall be placed closely together on the prepared cushion and no joint shall be more than ⅛ inch in width. Nothing but whole blocks shall be used except in starting a course, or in such other cases as the purchaser may direct; and in no case shall the lap be less than 2 in. Closures shall be carefully cut and trimmed by experienced men. The portions of the block used for the closures must be free from checks or other fractures and the cut end must have a surface perpendicular to the top of the block and cut to the proper angle so as to give a close, tight joint. The angle of the course with the curb shall be determined by the purchaser. After the blocks are placed they shall be rolled parallel and diagonal to the curb by a tandem roller weighing between 4 and 7 tons, until the surface becomes smooth and is brought truly to the grade and contour of the finished pavement. In case of a mortar bed the rolling shall be completed before the mortar bed has set. All mortar that has set before the blocks are in place and rolled shall be discarded and replaced by fresh mortar.

"Filler. After the rolling is completed the joints between the blocks shall be filled with either a pitch or asphalt filler as specified hereafter. The filler shall be brought to the proper temperature and poured into the joints, and any filler on the surface of the pavement must be spread as thin as possible by means of squeegees. The receptacle in which the filler is heated shall be equipped with suitable thermometers. After the joints are filled as described, the surface shall be completely covered by a thin coat of coarse, clean, dry sand, and a similar sand shall be spread over the pavement, if required by the Engineer, before the acceptance of the pavement.

"PITCH FILLER. The filler shall be a straight run residue obtained from the distillation of coal tar, and shall comply with the following requirements:

1. The melting point shall not be lower than 60° C (140° F), nor higher than 66° C (150° F).
2. It shall contain between 22 and 37% of free carbon insoluble in hot chloroform and benzol.
3. The specific gravity at 25° C (77° F) shall not be less than 1.24 nor more than 1.32.
4. The specific gravity of the distillate up to 355° C shall not be less than 1.07 at 38° C (100° F), compared with water at 15.5° C (60° F).

The pitch shall be heated to a temperature not exceeding 163° C (325° F), and shall be poured at a temperature between 121° and 149° C (250° and 300° F).

"Asphalt Filler. The filler shall be an asphalt filler and shall comply with the following:

1. It shall contain at least 98% of bitumen soluble in carbon disulphide.

2. It shall have a penetration within the following limits: When tested for 1 min at 0° C (32° F) under 200 g, 10 to 20; when tested at 25° C (77° F), for 5 sec under 100 g, 30 to 50; when tested at 46° C (115° F), for 5 sec under 50 g, 150 to 300.

3. It shall show a ductility of at least 30 cm when tested at 25° C (77° F).

4. When 50 g are heated in an open tin to a temperature of 163° C (325° F), for 5 hr, the loss shall not exceed 1% and the penetration at 25° C (77° F) of the residue left after such heating must not be less than two-thirds of the penetration of the original asphalt cement before such heating when tested at 25° C (77° F).

"Sand Filler. After the rolling is completed the joints between the blocks shall be filled by sweeping dry clean sand into them, after which the surface shall be covered to a depth of about 1/2 in with fine sand. This sand is to be left upon the pavement for such a time as may be directed by the City, after which it shall be swept up and taken away by the Contractor.

"Blocks on Grades. When the blocks are laid on streets having grades of 3% or over, it is desirable that the blocks be spaced by laying creosoted wood lath, about 5/16 in thick, between each course. The space above the laths shall then be filled with heated crushed stone, containing no dust, and bituminous filler as specified above. The bituminous filler shall first be poured into the bottom of the joint, care being taken to get none on the surface of the pavement. The crushed stone shall then be swept into the joint and the space around the stone filled with a bituminous filler to the top of the joint. It is essential in open joint pavement to drive together the blocks every four rows to prevent tipping of the individual blocks."

11. Construction Cost Data

Minneapolis. The detailed cost of wood block pavements, where the work has been done by city employees for many years, not including foundation, is as follows:

1 superintendent, part time	$1.00
1 timekeeper, part time	0.50
1 foreman	4.50
1 team	5.00
1 roller man	4.00
1 watchman	2.50
2 tar men	5.25
1 inspector	2.50
1 sweeper	2.50
3 men throwing to pavers	7.50
6 wheelers	15.00
4 block layers	12.00
2 trimmers	6.00
1 line man	2.50
1 bed man	3.50
4 sand spreaders	10.00
1 concrete sweeper	2.50
32	$86.75

This organization will lay on an average of 1500 sq yd per day, under good conditions. Average, $0.0578 per sq yd. The entire cost of laying the pavement, not including foundation, is as follows:

Hauling blocks	$0.066
Laying blocks	0.058
Miscellaneous, clearing street, moving on and off of tools	0.024
Cushion sand $0.75 per cu yd	0.024
Pitch, $12.00 per ton f. o. b	0.055
Creosoted blocks, $1.40 per sq yd, f.o.b	1.400
Total	$1.627

The blocks used were southern yellow pine 4 in deep, with a treatment of 16 lb per cu ft.

New York City. The cost of laying 800 sq yd follows:

1 foreman	$4.00	
1 bedmaker	3.20	
2 men on striking board	6.40	
10 laborers making and spreading mortar bed	17.50	
4 pavers, one cutting in	12.80	
16 laborers handling blocks, etc	28.00	
1 roller man	5.00	
1 helper	2.50	
1 laborer cleaning up	1.75	$81.15
The cost of joint filling follows:		
1 laborer tending kettle	2.00	
2 laborers carrying pitch	4.00	
2 laborers pouring	4.00	
4 laborers squeegeeing	8.00	18.00
Total labor		$99.15

Cost of labor per yard	$0.124
Cost of mortar bed per sq yd	0.090
Cost of pitch per sq yd	0.075
Cost of 4-in block, 20-lb treatment per sq yd	2.000
Total	$2.289 per sq yd

Wenatchee, Wash. (36). Cost details of laying 27 595 sq yd of wood block pavement on Wenatchee Ave. in 1913. Construction: 4 in, 16 lb creosoted Douglas fir blocks, joints filled with asphalt; 1 in sand cushion; 5 in 1 : 3 : 6 cement-concrete foundation. Common labor, $2.50 per 8-hr day; block layers, $10.00 per 8-hr day. Roller rent $3.50 per day. Wood blocks, $1.75 per sq yd, f.o.b. Wenatchee plus $1.10 per thousand for unloading and hauling.

Cost of Materials

		Amount Used per Sq Yd	Cost per Sq Yd	
Foundation	Gravel, $1.30 per cu yd	0.0973 cu yd	$0.1263	
	Sand, $1.00 per cu yd	0.0486 cu yd	0.0486	
	Cement, $2.10 per bbl	0.125 bbl	0.2625	
	Water	....	0.0100	
	Mixer (interest and depreciation)	....	0.0152	
Cushion	Sand, $1.00 per cu yd	0.0278 sq yd	0.0278	
Blocks	Blocks, $1.794 per sq yd	42.25 blocks	1.7940	
	Asphalt filler, $37.75 per ton	0.0031	0.1153	
Total cost of materials per sq yd				$2.3997

Cost of Labor

		Cost per Sq Yd	
Foundation	Mixing	$0.0523	
	Placing	0.0205	
Cushion		0.0141	
Blocks	Laying	0.0160	
	Helping	0.0435	
	Rolling	0.0159	
	Filling	0.0599	
Total cost of labor per sq yd			$0.2232
Total cost of pavement and foundation per sq yd			$2.62

England. Swedish deal blocks laid on concrete with a cushion coat of asphalt cost $3.08 per sq yd and had an average life of 7 years, and cost $0.209 annually for repairs. Creosoted blocks, lime joints, cost $2.95 per sq yd, with an average life of 8 years, and cost $0.204 per year for repairs. Creosoted blocks with asphalt mastic joints cost $3.55 per yd, with an average life of 8 years, and cost $0.24 per year for repairs. Pitch-pine blocks cost $2.91 per sq yd, with cement joints, with a life of

9 years, and were maintained at an expense of $0.088 per sq yd per year for repairs. The life of these foreign pavements is estimated for the traffic standard of 750 tons per yard of width per day.

Table I.—Character and Cost of Wood Block Pavements in 1915 in Several Cities

From *Engineering and Contracting*, April 5, 1916

City	Sq Yd	Price* per Sq Yd	Guarantee Years	Kind of Filler	Concrete Foundation

MAINTENANCE

12. Bleeding

Two of the greatest objections to treated wood block pavement are its liability to bleed when first laid and its occasional bulging due to the expansion of the blocks caused by the absorption of water in wet weather. In New York City there has been some trouble on this account, but not to such an extent as in the West. One reason for the blocks in New York not bleeding as much as those in the West is probably because of the fact that the joint filling in New York has generally been sand, while in the early pavements of Chicago it was pitch or some other bituminous material. By this term is meant the exudation of the preservative during warm weather soon after the pavement is laid. This occurs in different degrees in different cities under different conditions. In Cincinnati, Ohio, and Chicago there has been some trouble on this account, and many have been the complaints of the property owners because of this, as it makes the pavement very sticky, and is therefore tracked into residences and business houses. This bleeding occurred slightly with the creo-resinate process,

but in an entirely different way. The exudations then were altogether of rosin, which soon cooled and formed a hard, glassy substance, which was exceedingly slippery for horses. That, however, was soon crushed and worn out by heavy traffic. On the first pavement laid in Brooklyn, N. Y., there were quite a number of complaints on account of slipperiness soon after the pavement was laid. This was on a residential street, where the traffic was light, but even then the complaints soon ceased. One of the problems of the wood block manufacturer is to overcome this tendency of the blocks to bleed. Just what causes it or accelerates it is uncertain. It is probable, however, that the greater the treatment given the blocks the more they will bleed, no matter what the preservative. The advocates of the light oil claim that there will be very little bleeding with that material and that the trouble is caused almost entirely by the mixture of the tar with the creosote oil. Others think that the bleeding is caused almost entirely by the expansion of the blocks, the pressure forcing the preservative to the surface. The Chicago specification requires oil to be of 1.08 to 1.12 specific gravity, and provides that it shall be an absolute distillate of coal tar. This means that no filtered tar can be mixed with the oil itself. Since the use of this oil the trouble from bleeding has almost entirely ceased. It occurs during the first warm days of spring. On a street that is partially shaded the bleeding often occurs very freely on one side and not at all on the other. This would seem to refute the argument of those who claim that bleeding is caused by the expansion of the blocks. This exudation is not entirely bad, as it brings the preservative to the surface and so renders the top of the block absolutely watertight. When it occurs to a great extent it can be overcome by sprinkling the surface of the pavement with sand, which is scraped off after the preservative has been absorbed. Some trouble occurs on this account in the European cities, but not much, as the treatment of the blocks is so light.

Howell (26b) states that: "The bleeding was extremely noticeable on several warm days when the thermometer ranged from 32° to 36° C (90° to 97° F) in the shade, and possibly 46° to 49° C (115° to 120° F) on the pavement, but by causing the blocks to be covered with a thin coating of sand, no unpleasant conditions followed. During the summer and fall the pavement was sprinkled quite frequently. Early in the fall a thick coating or crust formed on the top of the blocks, caused by the oozing out of the preservative and its coming in contact with the sand. The contractor scraped this off and removed it from one street on several occasions. This coat did not stick to shoe leather to any appreciable extent, and did not cause any unfavorable comment from storekeepers in regard to being tracked into buildings and soiling the floors, as was the case with the wood block pavement on Market St., Philadelphia, a few years ago."

Teesdale (41a) has described, as follows, an investigation of bleeding which was intended to include those factors entering into the selection of material and its treatment at the plant that might have an influence on bleeding. The investigation covered, (1) Species and rate of growth. (2) Moisture condition of the wood when treated. Green and air-dried wood was tested. (3) Character of preservative used. A distillate creosote oil and a mixture of this with tar, the latter intended to be representative of the grade of paving oil in general use, were tested. (4) Manipulative methods employed in treatment, especially the use of steam and vacuum treatment and preliminary air pressures. In addition, tests were made to determine the effect of varying the absorption of preservative, and of subjecting treated blocks to external pressure, a condition sometimes obtained in a street when the expansion trouble exists.

"MATERIALS USED. Wood: Green long-leaf pine and thoroly air-dried long-leaf pine, rapid growth loblolly pine, and eastern hemlock blocks, 4 in by 8 in by 4 in were used in the work. The long-leaf pine was regular paving block stock; the other material was sawed from ties. Preservatives: Two preservatives were used in the

investigation of bleeding. One was coal tar creosote with a specific gravity of 1.07 at 60° C (140° F). The other was a 50% mixture of this creosote with a by-product coke-oven tar having a specific gravity of 1.17 at 60° C (140° F), and containing about 6% free carbon. This mixture was believed to be comparable to much of the paving oil used for treating blocks.

"METHOD OF MAKING BLEEDING TESTS. After treatment, the blocks were placed in an oven in tin boxes, and subjected to a constant temperature of 49° C (120° F), until the oil ceased to bleed from them. Blotting paper was used to absorb the oil as it came from the blocks. Weights were taken at suitable intervals, corrections being made for losses by volatilization. In the data presented, an average of two blocks was taken in each case.

"The results indicate that a preliminary vacuum especially is a very important factor in treating air-dry paving blocks if bleeding is to be reduced. Steaming, when used without a vacuum period, was not very efficient in reducing bleeding when creosote was used. With the tar and creosote mixture, however, the reduction in bleeding was very marked. Steaming evidently has a much greater effect on the tar and creosote mixture than on the creosote. With either green material, and with either the creosote or the tar and creosote mixture, bleeding was greatly reduced when both steam and vacuum treatments were applied. It will be noted that the loblolly pine bled very much more than the long-leaf pine when no preliminary vacuum was used. When preliminary vacuum was used, the absorption could not be controlled and 40 lb per cu ft were absorbed. While the percent of bleeding was reduced the total amount of bleeding was, therefore, still very large. Bleeding was materially increased when absorption was increased, especially when more than 16 lb per cu ft were injected, or when the tar and creosote mixture was used. The effect of outside pressure, intended to show the effect of the expansion of blocks in the street on bleeding, did not appear to have much influence on bleeding. The blocks in this case were compressed in an iron clamp until the wood was crushed. This extreme condition would not be reached in the street. Nevertheless, bleeding was not greatly increased. When no preliminary vacuum or steam treatments were used, the blocks treated with tar mixtures in most cases bled considerably more than those treated with creosote; this was true regardless of species. Steaming blocks prior to treatment appeared to have a very marked retarding influence when tar was used. The tar appeared to dry in the outer pores of the wood, forming a mat that retarded bleeding. The use of a final steam bath did not influence the bleeding materially, but removed carbon from the surface and greatly improved the appearance of blocks treated with the tar mixture. All of the results seem to indicate that bleeding is caused to a large extent by the expansion of air in the wood cells. Other contributing causes which no doubt aggravate bleeding are expansion of the preservative in the wood, external pressure exerted upon the blocks, excessive absorption of preservative by some of the blocks, and the use of rapid growth woods. Sapwood is also a factor, largely because of the excessive absorption of oil that it takes."

Weiss (7) states, that "From observations and tests made by the author it is believed that bleeding can be eliminated if (1) only slow-grown wood is used for the blocks; (2) if green timber or steamed seasoned timber is used; (3) if a strong preliminary and final vacuum is drawn before and after the oil is injected; (4) if when tar is used the blocks are steamed slightly after the oil is injected; (5) if the penetrations are made complete; (6) if impregnations no greater than 16 lb per cu ft are given; (7) if straight coal tar creosote or coal tar creosote containing only small amounts of carbon-free tar is injected; (8) if the blocks are not laid too close together; (9) if excess tar or pitch is not poured between the joints. All of these requirements can be easily met without added cost."

It would seem that, without question, with a few years more experience it will be easy to determine what is the best method of reducing bleeding. The conclusions of Weiss seem logical, and, as he states, his conditions can be complied with without extra cost.

13. Swelling

The bulging of wood pavements on account of the expansion of the blocks has caused a great deal of trouble and has retarded to quite an

extent the use of this material in pavements. Wood of itself is a very unstable material, changing a great deal according to its moisture content, and it is necessary to have the blocks so treated that they will not unduly expand or shrink according to climatic changes. When the wood pavements were laid in Brooklyn, N. Y., in 1902 to 1904, inclusive, with the creo-resinate process, provision was made for a water absorption of not more than 3%, without any expansion joint whatever, and on the streets where city inspection prevailed no trouble from expanding or bulging has occurred.

In Germany, in order to overcome the swelling or bulging of the pavement in wet weather, in some cities the surface of the pavement is kept moist and the surface tarred so that the water cannot penetrate into the blocks. The wood pavements of Berlin in summer, when water is plentiful, are watered three times a day.

In Paris much trouble has been caused by this bulging. This is not strange when it is considered that up to 1913 the blocks contained only 3 lb of oil per cu ft. Tur (43), the Engineer in charge of wood pavements in Paris, in a discussion on bulging, says:

"In practice it is impossible to foresee the circumstances under which any road will absorb water and will expand. The phenomenon depends on the quality of the wood, the quantity of water with which it was impregnated at the moment of laying and the atmospheric conditions prevalent from that time on. Thrusts are usually exerted perpendicularly to the axis of the road. They usually displace the sidewalk, curbs, and quite often the tracks of the tramways. Sometimes, too, they manifest themselves in a longitudinal direction by more or less extended upliftings of the entire pavement. The displacement of the curbs and the parts near the flagging never cause any noteworthy trouble, nor do the partial liftings of the wood pavement. The danger of damage from this cause can be reduced by sprinkling the blocks thoroly before laying them. In order to facilitate repairing of the sidewalks, a joint filled with sand is made, as we have already said, along the curbs. As for the liftings, which occur more rarely, they are easily removed by extracting one or two rows of blocks. Unfortunately the system which will render wood pavements entirely harmless has yet to be found. The effect of sprinkling the blocks before laying can never be other than temporary, and it is often ineffective."

Experience in the United States.

Roberts (34) has given the following facts relative to a striking example of expansion in wood pavement which occured in 1911 in the City of Longview, Texas. The street paved had a roadway of 70 ft, and contained 16 000 sq yd. The pavement was laid with a great deal of care on a concrete foundation, with a 1-in sand cushion and a 2-in expansion joint on each side of the roadway. The summer of 1913 was exceedingly hot and dry, there being no rain for 65 days prior to Sept. 7, when a severe rain storm set in, which continued for 8 days, during which time 9.37 in of rain fell. On the second day of the rain the blocks began to swell, so that street-car traffic was stopped and ordinary street traffic seriously hampered. The breaking up of the pavement extended transversely and longitudinally along the street, the failure across the roadway being the greater. The expansion across the roadway was measured and was found to be about 8¼ in. On Sept. 14, when the storm was nearly over, three sample blocks were taken and weighed, the mean weight being 56.9 lb per cu ft. On Oct. 6, after 23 days' drying at an even temperature of 21° C (70° F), these three sample blocks were again weighed, on the same scales, and showed an average weight of 47.4 lb per cu ft. From over 9 in of rain these blocks had absorbed an average of 9½ lb of water per cu ft. After drying 14 days more a further loss of 4.3 lb was shown, the mean weight then being 43.1 lb per cu ft, a total loss of 13.8 lb per cu ft after 37 days' drying.

The causes of the phenomena, in the order of their importance, were decided to be: (1) Extreme weather conditions of 65 days' drought followed by 8 days of rain in which 9.37 in fell; (2) the removal of the protective sand covering too soon after the completion of the pavement; (3) the use of extremely fine sand for the cushion;

(4) laying the blocks too tight; (5) neglect to sprinkle and oil at intervals; (6) pavement of this type too wide (70 ft) for the traffic that it has to carry.

Green (22), reporting further on this, states that the timber was treated with 20 lb per cu ft of creosote oil having a specific gravity of 1.05. The timber itself was almost entirely short-leaf yellow pine, weighing about 32 lb per cu ft when seasoned. The blocks were laid close, but were not tightly driven as a rule. The joints between the blocks and rows were filled with sand. When the blocks were examined it was found that nearly 50% of the original oil with which they were treated had evaporated.

Howell (26a) states that the Newark specifications provide for expansion as follows: "(1) By providing for expansion joints along the curbs, 1½ in wide, to be filled with a suitable bituminous filler capable of passing a good penetration test; (2) by laying the blocks comparatively loose in the pavement in order not to have any tight joints, sand being carefully broomed into the joints; (3) by soaking all of the blocks in 40 or 50 barrels, used as tubs, in which the blocks were required to be submerged in water for 10 min before laying."

The theory of soaking the blocks in water is undoubtedly that they will expand, so that after being laid in the pavement any further expansion will not cause bulging. If this treatment should be satisfactory it would be a simple matter to provide for it, but it would hardly seem that a block treated with 18 lb of creosote oil would swell to any appreciable extent by an immersion of 10 min in water. Howell stated that up to Dec., 1914, there had been no real trouble on account of bulging, except along the railroad tracks where the water got under the blocks.

Teesdale (41a) states regarding experiments on swelling, that "The first series was made to determine the effect on swelling of various percentages of tar, and also of free carbon in mixtures of tar and creosote. The second series was made to determine the influence of varying the method of treatment on swelling. All of the blocks in the first series, and one-half of those in the second series, were soaked in water after treatment until they ceased to expand. In order to correlate these results more closely with service conditions, the remainder of the blocks in the second series were, therefore, placed on the sand cushion and sprinkled with water twice each day until they ceased to change in size. Two sticks of thoroly air-dried long-leaf pine were cut into blocks 4 by 4 by 8 in. After the blocks were cut they were piled in the laboratory for several months before treatment to insure a uniform moisture condition. For each treatment given one block was used from each stick, thereby giving two blocks treated with the same preservative.

"The following preservatives were used in this experiment:

1. A coal tar creosote having a specific gravity of 1.07 at 60° C (140° F). The same as used in the bleeding test.

2. A by-product coke-oven tar containing 6% of free carbon and having a specific gravity of 1.184 at 60° C (140° F). The same as used in the bleeding tests.

3. A by-product coke-oven tar containing 16% of free carbon and having a specific gravity of 1.232 at 60° C (140° F).

4. A gas-house tar containing 30% of free carbon and having a specific gravity of 1.273 at 60° C (140° F)."

After detailing the methods of conducting his work, in the discussion of his results he says: "It is evident that the rate of swelling was considerably retarded in the treated blocks, and that the maximum swelling was not as great as that obtained on untreated blocks. The maximum swelling of untreated wood was reached in 40 days, while from 5 to 10 months were required to reach a maximum in the treated blocks. Blocks treated with mixtures of carbon-free tar and creosote showed a slower rate of swelling as the percent of tar in the mixture increased; this was not marked, however, until from 50 to 75% of tar was used in the mixture. In most cases the maximum swelling of blocks treated with tar mixtures was from 10 to 25% less than in those treated with creosote. There was also considerable difference in the amount of swelling obtained in blocks treated with different kinds of tars. Air-dry long-leaf pine, green long-leaf pine, and air-dry rapid growth loblolly pine were used. All of the blocks were cut from the heart-wood. The seasoned material was obtained in an air-dry condition, and after being cut into blocks, was seasoned in the wood preservation laboratory for several months before being treated. Creosote, and a mixture of 50% creosote and 50% by-product tar were used. These oils were the same as those used in the bleeding tests. The following treatments were made with each preservative on

seasoned long-leaf pine, using 10 lb and 16 lb per cu ft absorptions in each case: (1) No preliminary or final vacuum; (2) preliminary but no final vacuum; (3) final but no preliminary vacuum.

"The results are not very consistent, but they indicate that the air-seasoned long-leaf pine blocks treated with either oil did not swell as much if given a preliminary vacuum, as when no vacuum period or final vacuum was given. Also that blocks treated with the creosote and tar mixture swelled less than those treated with creosote, unless a preliminary vacuum was used. No difference in swelling was indicated between the 10-lb and the 16-lb treatment except that the results obtained from the latter were more consistent, due probably to more uniform penetration There is no indication that increasing absorption decreases swelling in either case. In general, the blocks treated with the creosote and tar mixture swelled less than those treated with creosote alone. Similar tests were made on green blocks. Practically no swelling was noted. Measurements were made on a few of the blocks placed on the sand cushion to determine the difference in swelling between the top and bottom of the blocks. In all of the previous tests the tacks were placed 1 in from the bottom face. In this test, additional tacks were placed 1 in from the top. The curves, as well as the appearance of the blocks themselves, show very strikingly the greater amount of swelling that occurred in the bottom of the blocks. This in some cases is very probably a cause of buckling, especially where the pavement has considerable crown, due to the upward force liable to be exerted if the bottom of each block expands more than the top. This is liable to occur if water penetrates the filler and reaches the sand cushion."

Among his conclusions he gives: "Increasing the absorption of oil above 10 lb per cu ft had but little influence in reducing swelling. No swelling was obtained in blocks treated in the green condition. It was possible to obtain the desired absorption by increasing the time and pressure of the treatment as the percentage of tar was increased. The penetration of preservative was more uneven as the percentage of the tar in the mixture was increased. The decrease in swelling obtained by varying methods of treatment, or by using tar mixtures, does not seem to be sufficient in itself to prevent expansion in street pavements. The use of green material was the most effective of the methods tested. These tests seem to indicate that long-leaf pine paving should be treated in the green condition after being well steamed. All blocks, even if thoroly air-seasoned, should be well steamed. While it is true that a preliminary and final vacuum greatly retarded bleeding and to some extent the swelling of air-seasoned wood, a preliminary vacuum will tend to make the absorption of oil too rapid during treatment, resulting in uneven penetration. A steaming period is, therefore, advisable to render the absorption less rapid and allow a longer and more intense pressure period to be applied. Furthermore, if seasoned blocks are steamed, they will take up moisture and expand and should be less liable to give trouble from swelling after laying in the street. For these reasons it would be preferable to treat green material when it is possible to obtain it."

He also says that if the blocks cannot be laid soon after treatment, they should be covered and perhaps wet down occasionally to prevent them from drying out. Also, that absorptions of over 16 lb per cu ft hardly seem necessary; that the reason why some pavements bleed while others do not may be often traced to the method used in treatment; that the tests do not indicate that the use of tar mixtures will prevent swelling, altho they tend to retard it; that the tests indicate that increasing the absorption of oil above 10 lb per cu ft does not tend to appreciably decrease swelling; that in drawing up specifications for treating blocks the waterproofing effect of the oil should not receive much consideration, the main points to be considered being to have sufficient oil of a good grade to obtain a thoro penetration in order to avoid decay, and to specify a method of treatment that will not cause the blocks to bleed. The tests also indicate that swelling should be controlled principally by having the blocks in the green condition when laid in the street, and by taking special care with the filler and method of laying so that water will not penetrate to the bottom of the blocks.

Weiss (7), in speaking of expansion, says: "It is wasted effort to try and make the blocks non-expansive, for no matter how much oil is forced into them they will absorb more or less water in time. Furthermore, the oil and wood will expand due to rise in temperature. Best practice, therefore, is to keep the absorption of water to a minimum by proper treatment and to allow for expansion by carefully laying the pavement as described above."

14. Slipperiness

One of the great objections to wood pavement is its slipperiness. This is a valid objection, as creosoted wood pavement is probably more slippery than any other kind of pavement. This, however, depends a great deal upon conditions, as if the pavement be dry, there is no trouble whatever, but when somewhat moist, especially if not clean, there is apt to be trouble on account of lack of foothold for horses. So that, in considering this material for a street, special care must be given to a study of conditions, the rate of grade, and the amount and character of traffic. It may be said that in the west, especially at Minneapolis, Minn., and Great Falls, Mont., very little trouble has been experienced on account of slipperiness. This may be due to the natural dryness of the atmosphere. In New York City, however, slipperiness on wood pavements is very observable. In such a climate it is advisable not to lay wood on grades of more than 2% without some special treatment. This general rule, however, can be modified if the street is one that does not have a large amount of continuous traffic, or if the traffic can be easily diverted in case of emergency to adjacent streets. On such a street the few days in the year when a wood pavement would be slippery would not be so important, but where a street is used constantly by heavy traffic every day despite the weather, it is extremely necessary that every care should be taken to prevent slipperiness. There are several ways, however, of mitigating this nuisance of slipperiness. In foreign countries the practice of sprinkling the pavements with sand is much more general than in the United States. The wood pavements abroad, too, are softer, so that sand or gravel spread upon the pavement is driven into the blocks by the traffic to a much greater extent than would be the case with the yellow pine blocks of America. The officials of American cities have not generally taken up the plan of sanding the streets when slippery. If this were done systematically much of the trouble which occurs from slipperiness would be avoided, without much expense.

Fig. 3

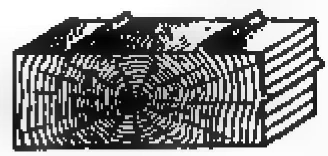

Fig. 4

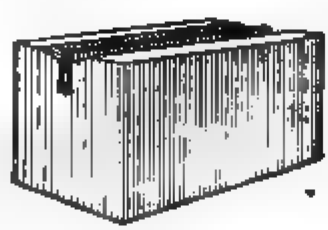
Fig. 5



Size of Block
4 by 5 by 12 in

Fig. 6

Kreolite. A form of wood pavement that has recently come into use in this country is known as Kreolite. The blocks are the same as those for ordinary wood pavement, excepting that they have lugs on one side and one end about ¼ in long. The object of the lugs is to separate the courses so that the pavement will not be so slippery, and also that there may be an expansion joint between each course of blocks, the idea being that the lugs will crush and so take up the natural expansion of the block itself, thus preventing bulging in the pavement. It is also claimed that, as treatment of

over 12 lb per cu ft is mainly to prevent bulging of the pavement, with this system a much less amount of preservative can be used, thus cheapening the pavement in that respect. This pavement has been used to quite an extent on bridges and in certain cities of the central west. Fig. 3 shows a portion of this pavement laid, and Fig. 4 one of the blocks. A device which has been gotten up to prevent slipping consists of grooving the upper face of the block and inserting in the groove a steel grid so that its top will come just above the surface of the block itself. When this pavement is laid on grades which are somewhat too heavy for the ordinary wood block, every third course is laid with the gridded blocks; but if the grade is very steep, every other course is laid with the grids. The extra cost of this pavement is about 65 cents per sq yd when one course in three is used with the grids, and $1 per sq yd when every other course is gridded. The blocks are treated in the usual way, the grids being simply to afford a foothold for the horses. Fig. 5 shows a portion of a pavement laid with three-and-one courses, and Fig. 6 a block with the grid inserted.

15. Maintenance Cost Data

Observations made by the Bureau of Highways, Borough of Manhattan, New York City, show a wear on the granite pavement on the approach to the Brooklyn Bridge of 0.0490 in per 100 tons, but for the wood pavement on the Queensboro Bridge a wear of 0.0203 in per 100 tons; on the Washington Bridge, 0.0231; on the Metropolitan Ave. Bridge, 0.0231; on the Meeker Ave. Bridge, 0.0300. On 20 London streets paved with wood the wear was reported as 0.0615 in per 100 tons, and on the Minneapolis, Minn., experimental pavements, previously referred to, 0.0222. It will be noticed that the wear on the wood pavement of this country is very uniform, and that it is about one-half the wear on the granite pavement, and one-third the wear on the London pavements. This is not surprising for the London pavements, as the wood there is much softer and wears more rapidly than American wood. It is, however, somewhat surprising that the wood should wear less than the granite.

Minneapolis, Minn. (19d). "The following is the cost in cents per square yard per year for repairs of creosoted wood block pavements in Minneapolis for the various years, and also shows the total yardage in place on Jan. 1st of each year:

Year	Total Sq Yd	Maintenance per Sq Yd in Cents
1907	210 464	0.012
1908	312 815	0.085
1909	457 583	0.052
1910	600 922	0.064
1911	757 472	0.294
1912	928 726	0.162
1913	1 060 688	0.193
1914	1 195 932	0.254
1915	1 381 605	0.239
1916	1 516 819	0.054

London. The cost of repairs varies very much with the method of making them. A contract was made to keep Piccadilly and part of Kings Road in repair for 15 years for 3s. (73 cents) per yd per year, when the Engineer estimated that its cost would not be more than 2s (49 cents). The annual cost per square yard for a plain deal, spread over 15 years, ran 1s. 8¾d. (82 cents), with a traffic of 279 tons, to 3s. 2d. (77 cents) for improved pitch-pine, with a traffic of 558 tons per yd per day. These figures were made in 1884. In 1893 a portion of the Euston Road was paved with wood;

63 ft with yellow deal, 62 with Karri, 49 with yellow deal, and 63 with Jarrah. After 3 years' time the wear was found to be 1/4 in on Jarrah and Karri, and 1 3/8 in on the deal. From observations taken, the traffic was found to be 575 544 tons per yd of width per annum. On another portion of the same road the wear was 1/5 in per annum with a traffic of 411 318 tons. Tottenham Court Road, which was paved with Jarrah blocks, showed only 1/4 in of wear after 3 years, with greater traffic than Euston Road, and on the Westminster Bridge Road, after nearly 7 years of wear, the Jarrah blocks had worn from 1 1/16 to 1 1/8 in, with a traffic of from 233 to 334 tons per ft of roadway in 12 hr.

Paris, in 1911, spent $902 989 for the maintenance of her wood pavements, which was nearly 33 cents per sq yd over the entire surface. This, however, provided for renewals as well as repairs. If the cost of repairs only were considered it would amount to 26 cents per sq yd over the entire surface maintained. Some idea can be had of the traffic of the Paris streets when it is known that the average life of wood in that city is 8 years, and, on the Arc de Champs Elysées, from 6 to 7 years only.

Petrograd. The wood blocks have a durability on an average of 3 years. It is estimated that the cement layer on the concrete will be renewed every 6 years, so that the annual cost of a wood pavement on concrete foundation would be 36 cents per sq yd. While the wooden foundation does not wear out, it does rot out, as its life is given as 6 years, so that the annual cost of a wood pavement on a wooden foundation is 46 cents per sq yd.

SECTION 19

STONE BLOCK PAVEMENTS

BY

GEORGE W. TILLSON

CONSULTING ENGINEER TO THE PRESIDENT OF THE BOROUGH OF BROOKLYN, NEW YORK CITY

GENERAL DATA

1. Historical Development

As stone was the most durable natural material that was generally known to the ancients it is not surprising that the first pavements were laid of that material. Just when the first pavements were laid is uncertain, but it is reported that stone roads were built between 1000 and 2000 B. C. The streets of Rome were said to have been paved in the 4th or 5th century after the founding of the city, while the first pavements in Paris were laid about 1184, when the city had a population of about 200 000. The Strand, London, was ordered paved by an Act of Parliament in the 14th century, and the streets outside of the city in the 16th century, altho it is stated that the first regular pavements were laid in 1533, when the city had a population of 150 000. It might seem strange in these days, when a modern city of 5000 people thinks it is not progressive unless it has street pavements, that cities should attain the size of Paris and London at the time mentioned before having improved streets, but in explanation it must be remembered that in those days streets were not used for vehicular traffic, as merchandise was generally carried on horseback and people were taken about the cities in chairs. As late as 100 years after the reign of Queen Elizabeth pack-trains were regularly used for commerce in England.

Character of Blocks. The early pavements were constructed of large, irregular stones, without much regard for smooth surfaces, the idea being mainly to keep what traffic did use the streets and roads out of the mud

and dust. Figs. 1 and 2 show the character of stone used in a road built by the Romans on the Septimer. While built of irregular stones, these roads were very substantial, often being laid in mortar and being really solid masonry constructions.

The streets of Pompeii, disclosed by recent excavations, show the class of stone used in the streets of that city, which incidentally are probably the oldest pavements that have been seen by people of the present day. These stones, comprising several square feet in area, were undoubtedly of lava, which would soon become smooth even under foot wear. They were laid with fairly close joints, but their condition indicates that they were not laid with regard to vehicular traffic. The roadway was narrow, and at street crossings large circular stones were placed at such distances apart that they could easily be used by pedestrians, but which would practically block vehicular traffic. In some instances the streets were so narrow that only one stepping stone was required, but on other streets more were required.

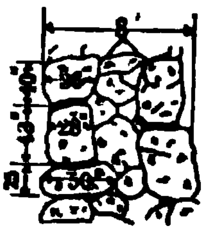

Fig. 1

As the needs of traffic and civilization increased the demand arose for improved streets, and consequently a better class of pavement, which

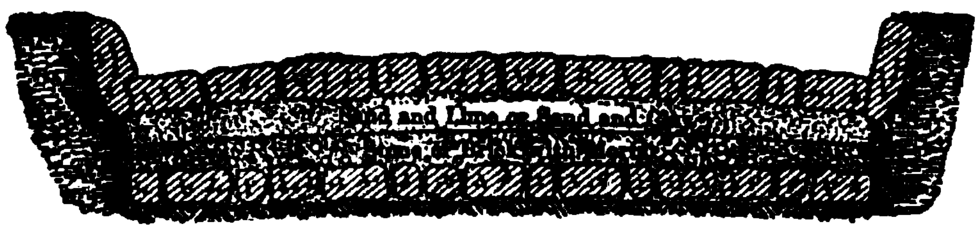

Fig. 2

required better blocks. Even after the blocks began to be improved they were of large size, especially in the Italian cities. Fig. 3 shows a typical street in Catania, Italy. The blocks of which the pavement is laid are of hard lava, 16 by 20 in in size and 8 in thick. In Palermo, Sicily, blocks were used to within quite recent date 18 by 24 in on top and from 8 to 10 in deep, while in Triest, Austria, they were from 24 to 60 in in length, 12 to 18 in in width and 6 to 10 in deep, and in Milan, Italy, they were also very large. When the Forum Trajanum was cleaned by the French in 1813 pavements were found on an average of 12 ft below the surface. The stones in the pavements were polyangular in shape, and were from 4 to 5 sq ft in size, and 12 to 14 in deep, laid with close joints. Modern blocks in Rome are described as being two cubes long, and, when set up, as having an area of 10 sq in. This would give a block about 7 in long, 3½ in deep, and 3½ in wide.

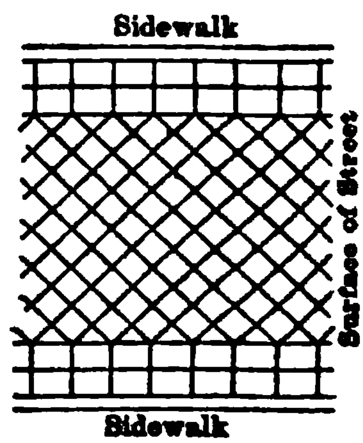

Fig. 3

Square granite blocks were first used in Westminster, England, in 1761, and in London in 1776.

In 1912 streets in New Orleans, La., were paved with blocks approximately 2 ft long and 1 ft wide. These blocks were said also to be 1 ft deep, so they could be, and were, turned over and relaid when the original surface became rough. These blocks came to New Orleans in vessels as ballast, some having been used for 60 years. In 1849 Broadway, New York

City, was paved as far north as Franklin St. with what was called Russ blocks. These blocks were from 2 to 3 ft square. About 5 years after this pavement was laid, it became so slippery that it was necessary to cut grooves in the blocks to give horses a foothold. Large blocks were not satisfactory, as, unless laid absolutely even and with close joints and on a solid foundation, under traffic they would soon become uneven and, unless of a particularly gritty character, would become smooth and slippery. Their use, therefore, was discontinued in progressive cities, as they could not be considered desirable from any standpoint.

In the course of development blocks of smaller size, approximately 6 and 7-in cubes were adopted in Europe and eventually in this country, taking the place of the cobblestone and forming the improved pavement. Later, came the modern oblong block, which was laid in New York City about 1877.

Guidet Pavement. In 1865 a patent was issued to Charles Guidet for laying granite pavement, the distinctive points of the pavement upon which the patent was based being: (1) Stones are bounded by six faces, the two opposite faces being parallel with each other; (2) the width of the joints running transversely to the street is comparatively wide; (3) the width of the joints running longitudinally to the street is comparatively narrow. A portion of Atlantic Ave., Brooklyn, N. Y., was improved with this pavement, and blocks measured there were found to be from 18 to 20 in long and from 5 to 6 in in width.

2. Foundations and Crowns

Foundations. Practically all large cities at the present time are using cement-concrete foundations. Vienna and Paris are, however, exceptions. The latter city in 1913 had but 8% of its stone block pavement laid on concrete. It is assumed, therefore, that all stone block pavements are laid on a concrete base. The thickness and composition of this base should depend upon the character of the traffic it sustains. If a pavement is practically a masonry construction, so that it is one broad sheet, the weight will be distributed over the base and not cause a great pressure upon any small portion. If, however, the blocks are not firm, so that a wheel load is liable to be transmitted from a block directly to the base, more careful attention must be given to the foundation. In Glasgow, where loads of 100 tons are carried upon wheeled vehicles, no thicker base than 6 in is ever used. It should be said, however, that the wheels upon which these loads are carried have tires 15 or 16 in wide, so that even with the heavy loads the weight is distributed over a considerable surface. It would seem, as a general proposition, that on a pavement where such loads were liable to be borne at very frequent intervals, special provision should be made for the foundation.

Crowns. Very few engineers agree as to the exact amount of crown to be given to a pavement, and they also vary it according to the character of the material. A pavement is laid in a street for use, and if it could be kept an absolutely horizontal plane it would be more desirable for traffic. It is necessary, however, to give it some crown in order to have the water run to the gutters. Any excess of crown beyond this requirement reduces the efficiency of the street to a certain extent. The worst possible way a horse can slip is sidewise, and for that reason the transverse slope should be kept as slight as possible to allow the water to flow to the sides freely. Formulas have been worked out by different engineers correlating the width of the roadway with the longitudinal grade, so that on a steeper grade the crown might be made lighter. It would

seem, however, that, as the only object of the crown is to allow the water to flow freely to the sides, a slope that would permit this on a light grade would not be detrimental to traffic on any grade, and it does not seem that there is any necessity of elaborate formulas to determine this. Fig. 4 represents the half cross-section of a stone block pavement.

Crowns for Different Widths of Roadway. Assuming the roadway of the street to be 30 ft wide, and adopting a total crown of 4 in, which does not inconvenience travel, the fall towards the gutter of the central one-third will be at the rate of 9 in per 100

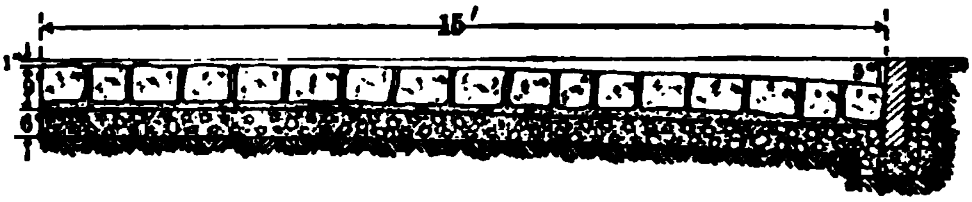

Fig. 4

ft, which is sufficient for drainage; the fall of the second one-third towards the gutter will be at the rate of 27 in per 100 ft; while that of the one-third adjacent to the curb will be at the rate of 44 in per 100 ft. Of course, the center of the roadway would be comparatively flat, but the rates above given will give sufficient drainage, altho possibly 5-in crowns could be used without damage with a stone block pavement. Table I gives the fall from the center to the gutter of each third of the roadway, with

Table I

Width of Road-way	Crown	Fall Towards Gutter in Central Third of Roadway	Rate per 100 Ft	Fall Towards Gutter in Second Third of Roadway	Rate per 100 Ft	Fall to Gutter in Third of Roadway Adjacent to Curb	Rate per 100 Ft
24 ft	3 in	1/3 in	8 1/3 in	1 in	2 ft 1 in	1 2/3 in	3 ft 6 in
30 ft	4 in	4/9 in	9 in	1 1/3 in	2 ft 3 in	2 2/9 in	3 ft 8 in
30 ft	6 in	2/3 in	13 1/3 in	2 in	3 ft 4 in	3 1/3 in	5 ft 6 in
36 ft	5 in	5/9 in	9 1/4 in	1 2/3 in	2 ft 4 in	2 7/9 in	3 ft 3 in
48 ft	6 in	2/3 in	8 1/3 in	2 in	2 ft 1 in	3 1/3 in	3 ft 6 in
60 ft	8 in	8/9 in	8 8/9 in	2 5/9 in	2 ft 3 in	4 5/9 in	3 ft 9 in

different widths and with different crowns. Under the heading of 30-ft roadways figures are given for the 6-in crown as well as the 4-in, showing how very materially the side slope increases with the crown, and this side slope, in slippery weather, is much more damaging to horses than a straight horizontal slope. These figures are recommended as the proper crown on all level streets of improved pavements, except the 6-in crown on a 30-ft roadway. The curve of the pavement is in reality a parabola, but in the distance used is practically a circle. It can be best laid out on the crown by stretching a line from curb to curb, and measuring the ordinates down from the line at any desired interval according to the width of the street. The length of the ordinate can be determined by the simple formula $O = C\ (D/R)^2$, in which D is equal to the distance from the center to any point in feet, R equals one-half of the width of roadway, C equals the crown in inches, and O equals the ordinates in inches.

Relation of Crowns and Gutters. The foregoing principles will work out satisfactorily when the curbs are set at the same level on both sides of the street. It often happens, however, that on side hills where the natural slope of the ground is considerable, it is impracticable to have the curbs on the longitudinal streets at the same elevation, and sometimes there is a difference of 1½ or 2 ft. In an old, improved

section it is extremely difficult to vary conditions much in repaving without undue damage to private property. Slight inequalities in the curb are not very objectionable, and they can be equalized to a great extent by varying the depth of the gutters. On an ordinary roadway 30 or 40 ft wide, the depth of the gutter should not be over 5 or 6 in. If, however, the roadway be wider, it will possibly be advisable to make the gutter deeper, but only in very exceptional cases should it be allowed a depth of 9 in; and, on account of the liability of overflow in case of heavy storms, it should not have a depth of less than 4 in, except under extraordinary conditions. Too deep a gutter also makes too great a step for pedestrians. If it should be assumed, then, that the minimum depth is 4 in and the maximum 9 in, a difference of elevation of the curbs of 5 in can be overcome by making the depth of the gutter on the high side 9 in and on the low side 4 in. This would make the bottoms of the gutters at the same elevation. This method can be pursued on roadways 40 ft or more in width even when there is a foot difference in the elevations of the curbs. When, however, the difference becomes as great as 1½ or 2 ft, another method must be used. In such a case by making the highest part of the pavement one-fourth of the distance out from the highest curb, and then sloping regularly to the low side, very good results can be obtained with a roadway of 40 ft. In a case like this the height of pavement above the gutter on this quarter distance out from the curb should be a minimum elevation above the gutter, say 2 in, which, if the maximum depth of gutter be used, would make the highest part of the pavement 7 in below the curb. If the elevation of the lower curb were 2 ft below the upper and a minimum of 4 in in depth used, there would be a fall from the highest point of the pavement to the bottom of the gutter on the low side of 21 in, which would be equivalent to giving a roadway of 60 ft a crown of 21 in. This is excessive, and not desirable, but it is probably the best treatment of the surface that can be given; and if the lower curb be only 18 in below the higher, the fall will be only 15 in, which will not be particularly objectionable.

Effect of Car Tracks on Crowns and Gutters. This plan is based upon the understanding that no street-car tracks exist in the street. When, however, tracks are present, the problem is complicated and it is practically impossible to give a satisfactory treatment to the street surface. The general treatment, however, must be the same, namely, a deep gutter on the high side and a shallow one on the low side. While the rails of each track must be level, it does not follow that the tracks themselves should be at the same level, altho it is preferable that they should be. If the difference between the two curbs be excessive, it is permissible, tho not desirable, to lay the two tracks at a difference of elevation of 3 in, and it often happens that it is necessary on the high side to have the fall from the gutter to the tracks. On a 40-ft roadway two tracks will occupy practically 15 ft in the center, leaving but 12 ft on each side of the tracks, so that there is but small space in which to overcome the difference in elevations of the two sides. When extreme cases exist, great care should be taken to get every advantage possible in establishing the grades of the tracks so that the roadway may be as favorable to traffic as possible.

MATERIALS

3. Physical Properties of Rock for Stone Blocks

In order to make a good paving block, stone should be of an even texture, hard, tough, and durable. It should wear smoothly, so that the surface of the pavement will be practically of the same contour even after it is worn down to a considerable extent. This last quality is important and an exceedingly difficult one to obtain. Apart from its wearing qualities, it should be of such texture as to break smooth and easily, so that a well-shaped block can be obtained without too great cost for labor. It should have sufficient crushing strength to sustain easily, on the side of the blocks used, any load that might come upon it. It should not be too hard, otherwise it will wear smooth and be slippery, and unless the blocks are laid with close joints the edges will round off, giving the block the so-called turtle-back appearance and make the pavement rough and of a cobblestone character, even when the blocks are really not much worn. In

America, stone blocks are made of granite, sandstone, trap rock, and limestone, altho the latter two are used to so slight an extent that they need not be considered seriously.

Granite. This stone is found very widely scattered over the United States, and is very valuable as a paving material. It exists largely in New England, especially on the coast. It breaks freely and with a smooth fracture in most varieties so that it is easily cut up into the desired sizes for paving blocks; and, being on the coast, the blocks are cheaply transported, so that this material is used to a great extent in Boston, New York, Philadelphia, and other cities near the seaboard. It varies considerably in hardness, and in some cities this is recognized by specifying hard granite and soft granite, the idea being that on streets of lighter traffic a softer granite is not only just as good but preferable, as on lighter traffic streets the wear is not so great and the blocks maintain a smooth surface and one that is not slippery. If, however, the traffic is heavy, the hard granite should be used, and the slipperiness prevented as much as possible by the joints between the blocks.

In 1897 Kent Ave., Brooklyn, N. Y., was paved with granite on concrete, with one of the best granites that comes to the New York market. The street had two lines of street-car tracks, and was used at that time to a great extent by the sugar manufacturers in carting sugar. These loads weighed from 6 to 8 tons, and were generally driven along the street with one wheel on one of the rails, so that the outside wheels ran in the same place. In 6 months an appreciable rut had developed in the blocks and also in the cross walks, and employees of the sugar refineries were sent upon the street to divert the traffic. Even then ruts soon developed, as, on account of the car tracks and the heavy loads, it was not possible to use the street from side to side as it could have been used had there been no tracks. An ordinary granite block would have lasted a very short time.

A so-called granite, but really a jaspar, was used in Omaha, Neb., after paving work was begun there in 1883. This stone was exceedingly hard, but did not break very well, and, while it showed almost no wear under traffic, it became so smooth that long before it was worn out it had to be taken up on account of its extreme slipperiness.

Sandstone. There are three kinds of sandstone used to quite an extent in the United States: That which is known as Medina sandstone, found near Rochester and Buffalo, N. Y., and which furnishes the material for the stone pavements of those cities as well as of Cleveland; the Kettle River sandstone, which is found in Minnesota and is used to quite an extent in St. Paul, Minneapolis, and vicinity; the Colorado sandstone, which comes from the quarries near Denver and furnishes the stone for pavements in that city and in Omaha, Neb.

MEDINA SANDSTONE. This stone is generally deep brown or red in color, tho sometimes gray, the coloring matter being oxide of iron. The principal quarries are located between Brockport and Lockport, in Monroe and Niagara Counties, N. Y. It is found in thin layers, so that it is easily gotten out in blocks and at comparatively low cost. It has good crushing strength, but wears much more rapidly than does granite; it is said, however, to have lasted from 40 to 50 years in pavements in the cities where it has been used. It varies in hardness according to localities, and for that reason, when used in pavements, the blocks should all come from one quarry, or ledges of similar formation, so that the blocks will be of the same degree of hardness and the wear under traffic uniform. These blocks can be laid so as to be very smooth, and, on account of the character of the stones, they are never slippery.

KETTLE RIVER SANDSTONE. The quarries from which this stone is taken

are situated at Sandstone, Minn., about half-way between Minneapolis and Duluth. The stone is extremely gritty and somewhat harder than the Medina. It makes an exceedingly durable paving block, and is easily cut with smooth faces and sides. It has a compressive strength of from 12 000 to 13 000 lb per sq in. It is extremely popular as a paving material in the localities to which it is tributary. It can be laid with close joints, so that a very smooth surface can be obtained for the finished pavement.

Colorado Sandstone. This stone is found in Boulder County, Col., to a large extent. It varies in color from gray to light red, according to the composition of the iron compounds, altho the character of the two kinds is practically the same. It is found in layers from 1/8 in to several feet in

thickness, and splits easily along the cleavage planes, breaking readily at right angles, so that it is formed into good paving blocks without an undue amount of labor. It is hard and tough, and wears well and smooth in a pavement. It is never slippery, even when smooth, and when laid on an unyielding base will, after a little wear, present a smooth and pleasing surface. It has a crushing strength on the bed of 10 000 to 12 000 lb per sq in, and, on edge, a strength ranging from 12 000 to 17 000 lb per sq in.

Trap Rock. This material has never been used to much extent in the United States, except in cities near the Hudson River. It is found in great quantities on the west bank of the Hudson, and when the Belgian block was first introduced in this country, trap rock was almost entirely used for its manufacture. It is extremely hard and will sustain a large amount of traffic without much wear, but soon becomes smooth, and its character is such that it is made into smooth, well-shaped blocks only at great expense. A few blocks have been used of the oblong shape similar to those of granite, but, on account of the expense of manufacture, to a very slight extent, and its use has been discontinued almost entirely as a paving material.

Whin Stone is used in Glasgow for paving, but under specifications similar to those provided for granite. The City Engineer of that city, in writing to the American Consul, says of this stone: "Whin stone, principally from quarries around the city, is heavy and close grained, and, while not so lasting as granite, lasts as long under the lighter traffic to which it is subjected in the minor thorofares where whin paving is adopted. It is not so slippery as granite, and on this account is used in several of the heavy traffic streets where the gradient is pretty heavy. Whin metal, from the same quarries, is also largely used for macadamizing purposes."

Tests. The Spec. Com. Mat. Road Cons., Am. Soc. C. E. recommends that the following tests on stone blocks be made: Specific gravity, absorption of water, abrasion, toughness, hardness, and crushing strength. Methods for making the above tests are given in Sect. 11. Table II gives the crushing strength, hardness and toughness of rocks from several quarries where stone blocks are manufactured.

4. Manufacture and Size of Blocks

Manufacture of Blocks. Granite paving blocks are practically all made by hand labor; no machinery has yet been invented that will produce blocks satisfactorily and economically. It takes the best of stone that is carefully quarried on the rift to make blocks so that they will break clean and smooth. The granite is first quarried into dimension sizes from large masses of stone by day labor, generally in blocks 36 in on the rift for the width of the block and 40 in for the depth, all in random lengths, so that when the pieces are drilled and split, blocks from 4 to 4½ in wide and about 5 in deep will be produced. The stock is usually transported by railroad and dumped into the paving cutters' berths, so-called, and there drilled and fitted into the finished block. The paving block makers earn, on an average, $15 per week. The blocks are cut by the piece, for which the block makers receive from $25 to $26 per thousand for standard blocks. The average number a man makes in a day of 8 hr is about 100. The blocks are inspected from day to day as they are being made, and again when they are loaded into cars or on board vessels for transportation to the various cities. The improved blocks, 8½ to 12 in long, 3½ to 4½ in wide, 4¾ to 5¼ in deep, will lay about 28 to the sq yd; the special improved blocks, 6 to 10 in long, about 32 to the sq yd. The smaller the block, the closer the joint.

Size of Blocks. Just what is the best size for a stone block has not been determined by engineers, as their opinions vary to quite an extent, depending upon the exact character of the stone to be used and also upon the individual ideas of the engineers themselves. It is generally conceded, however, that for heavy traffic streets an oblong block is best.

LENGTH. As it is extremely desirable that there be as few joints as possible parallel to the line of traffic, the blocks should be made comparatively long. As, however, all streets are laid with a certain crown, the blocks must not be so long as to give an uneven bearing on the foundation or be liable to tilt or tip up under traffic, nor so long as to easily break when extremely heavy loads are driven over them. Also they should not be so long as to make a block that would be too heavy for pavers to handle easily.

WIDTH. The blocks should be of such width as to give a good foothold for horses. On account of the character of granite, for instance, the surface of the stone itself can offer but a slight foothold for horses. In cities most horse shoes are made without calks, and unless the horse is able to get a foothold in the joints between the blocks, especially after the pavement is somewhat worn, his efficiency as a draft animal will be very much reduced, and he will also be liable to slip and injure himself. The blocks, however, must not be too narrow, otherwise the joints would be too many and the blocks would be liable to be unstable on the foundation. In the determination of the width of the block, however, the character of the stone and the traffic should be taken into consideration. As the sandstones are so much less slippery than granite, wider blocks are permissible, and if traffic is not made up of heavy units, the necessity of joints for foothold for horses is not so great.

When, just previous to the Spanish-American War, a contract was made for paving in Havana, Cuba, the maximum width of blocks was made 3 in, because in that city mules were then mostly used for trucking, and their feet being so much smaller than those of the ordinary horse, more frequent joints were required in order to give them the necessary foothold.

The City Engineer of Newcastle-upon-Tyne, England, in speaking of width, says: (22) "A narrow sett is used in order to give better foothold and to obtain a neat appearance in the pavement, but if the sett is not unduly wide, these requirements can be obtained by a greater width than 3 in. Further, with narrow setts giving a correspondingly large number of joints, not only is the noise increased, but the strength of the whole pavement is reduced. With most descriptions of granite the waste of material in producing a sett 3 in in width is considerable. Consequently the cost is about 9% greater than in the production of a sett 4 in in width."

DEPTH. This is probably the most important dimension of the block, and two principles must be considered in its determination: (1) The kind of wear which the pavement must sustain when laid, (2) the stability of the block itself. Very few blocks in a granite pavement are worn out when it becomes necessary to relay the pavement as a whole, but in a series of years the blocks become displaced so that they get an undue amount of traffic, are worn off on the edges, and so become rough and unsatisfactory, when the actual loss in the depth of the blocks is very slight. Therefore what is required is to have a block that is sufficiently deep as to be stable and have sufficient strength to sustain the traffic. As a general rule, and in order to have stability, the depth of the block should be not less than the width, and preferably greater. If blocks are made 5 in in depth there will probably be no danger of crushing when either granite or the best sandstone is used.

When the oblong shaped granite blocks were first used in the United States, they were given a depth of from 7 to 8 in. The blocks, however, were laid on a sand

foundation, and it was thought that a permissible variation of 1 in would not be detrimental to the pavement, as the sand base would take up the inequality, and by allowing this variation the blocks could be made more cheaply. When, however, the concrete base was used and it was not necessary to have so much inherent stability in the block itself, a block of much less depth was used, and in 1912, after a conference between the engineers of New York City and vicinity and the material men furnishing the granite to this locality, the following specification was adopted: "Blocks shall be of the following dimensions: Not less than 8 nor more than 12 in long on top; not less than 3½ nor more than 4½ in wide on top; not less than 4¾ nor more than 5¼ in deep."

Another form of stone that can hardly be called blocks is used in Russia, making what is called kidney pavement. These stones are said to be of irregular form, either entirely undressed or little dressed. The kidney setts are divided by sizes into four classes: large, about 10 in in length; medium, about 8 in in length; small, about 6 in in length; and fine, about 4 in in length, and the setts are therefore used as large, medium, small, or fine. The medium and small kidney pavements are generally used for the traffic section, the large for paving slopes, and the fine for strips of road surface on which there is little or no traffic. Stones not very much better in character than those just described could be seen in the pavements of Baltimore in 1915.

Table III shows the sizes of blocks used in many of the principal cities in this country and Europe:

Table III

City	Length Inches	Width Inches	Depth Inches	Remarks
Boston	8 to 12	4 to 4.5	5 to 5.5	Special cut
	9 to 14	3.5 to 4.5	7.5 to 8	Large
Brooklyn, N. Y.	8 to 12	3.5 to 4.5	4.75 to 5.25

Dressing. After the size of the block has been determined, its character as to smoothness upon its different faces is very important. It can easily

be understood that, in order to have a smooth pavement, the blocks themselves must be smooth, and this applies not only to the top but also to the sides so that the joints may be even and filled with some material that will hold them securely in place. As the class of labor required in making blocks is expensive, an extra amount of work upon the blocks rapidly increases the cost of the pavement. As has been intimated, stones of different texture and character break quite differently, and this one fact often determines whether or not a stone will be suitable for paving material.

In the Conference of New York City Engineers and granite block manufacturers, this question was discussed to a great extent, as it was not desired to specify a block that would require so much labor as to make it unduly expensive even if it made a first-class pavement. The specification in this respect that was finally adopted was as follows: "The blocks shall be so dressed that, after laying, the measurement of the individual joint will show not more than ½ in in width at top and for a depth of 1 in, nor more than 1 in in width in any other part of the joint, provided that not more than one drill hole shall show on the side of the head and none on the end of the head of any block. The head of the block shall be so cut that it shall not have more than ⅜ in depression from a straight-edge laid in any direction across the head and held parallel to the general surface of the block." This specification has been practically adopted by cities in the vicinity of New York and also by the Association for Standardizing Paving Specifications. It was extremely desirable to adopt such a specification, as it made it possible for the granite men to make blocks that would be satisfactory, not simply for one of the cities which they supply, but for all, so that if the demand in any one place should be excessive, blocks originally proposed for one city could easily be diverted to another, thus avoiding any vexatious delays.

The Bureau of Highways, Brooklyn, N. Y., adopted the foregoing specification for grade 1 granite blocks, but for grade 2 granite blocks the specification says that they shall be: "Not less than 8 nor more than 12 in in length; not less than 3½ nor more than 4½ in in width, and not less than 7 nor more than 8 in in depth. The blocks are to be rectangular on top and sides, uniform in thickness, to lay closely and with fair and true surfaces, free from bunches."

Providence, R. I., in 1913 received bids for two kinds of blocks, being practically such as has been described for grade 1 and grade 2, Bureau of Highways, Brooklyn, and the price per thousand blocks was $1 more for grade 2 than for grade 1. The requirements were the same for the character of the stone. It must be remembered, however, that the blocks of grade 2 were very much larger than of grade 1, and, altho not so well dressed, would require more raw material and cost more to transport, which is an important item of granite block pavement. This probably accounts for the difference in price, as it would naturally be expected that the better blocks would cost more. As a matter of fact, in Brooklyn, where contractors buy by the square yard as laid in the pavement, the price for grade 1 blocks is materially more than for grade 2, as it requires 28 of the improved blocks per sq yd and only 22 of the ordinary.

5. Specifications for Stone Blocks

Am. Soc. Mun. Imp. 1916, Specifications for Granite Paving Blocks. "The paving blocks shall be of medium grained granite, showing an even distribution of constituent materials, of uniform quality, structure and texture, without seams, scales or disintegration, free from an excess of mica or feldspar, and equal in every respect to the sample in the office of the engineer.

"Tests. For heavy traffic the granite shall have a toughness of not less than 9 and a French coëfficient of wear of not less than 11. For medium traffic, the granite may have a toughness of not less than 7 and a French coëfficient of wear of not less than 8 if a cement grout filler is used. The above tests shall be made by the methods described in Bul. 44, O. P. R., U. S. Dept. Agr. The average of three tests shall be used for determining toughness and the average of six tests for determining the French coëfficient of wear. Contractors shall file with the engineer at or before the time of bidding, a certificate showing the name and location of the quarry from which it is proposed to obtain the blocks, also a certified copy of a report from the U. S. Dept. Agr., showing the toughness and French coëfficient of wear of the granite which it is

proposed to use. On or before the date of the letting, six specification blocks, made from the granite it is proposed to use, shall be filed with the engineer.

"SIZE OF BLOCKS. The blocks shall be of the following dimensions: Not less than 8 nor more than 12 in long on top; not less than 3½ nor more than 4½ in wide on top; not less than 4¾ nor more than 5¼ in deep. Note: When in the judgment of the engineer, a shallower block than that before specified is deemed desirable, a block 3¾ to 4¼ in wide, 3¾ to 4¼ in deep, and 7 to 11 in long, may be used, provided the granite has a sufficiently high factor of toughness and French coëfficient of wear.

"DRESSING. The blocks shall be so dressed that the faces will be approximately rectangular in shape, and the ends and sides sufficiently smooth to permit the blocks to be laid with joints not exceeding ½ in in width at the top, and for 1 in downward therefrom, and not exceeding 1 in in width at any other part of the joint. The top surface of the block shall be so cut that there will be no depressions measuring more than ⅜ in from a straight-edge laid in any direction on the top and parallel to the general surface thereof. Care shall be exercised in handling the blocks so that the edges and corners shall not be chipped or broken, as blocks otherwise acceptable may be rejected on account of spawling. The blocks shall be sorted and laid in courses of uniform width, except in special cases, as may be ordered."

Am. Soc. Mun. Imp. 1916 Specifications for Sandstone Paving Blocks. "The paving blocks shall be of sound, hard sandstone, free from clay, seams, or defects which would injure them for paving purposes, of uniform quality and texture, and equal in every respect to the sample in the office of the engineer.

"SIZE OF BLOCKS. The blocks shall be of the following dimensions: Not less than 8 nor more than 10 in long on top; not less than 3½ nor more than 6 in wide on top; not less than 4¾ nor more than 5¼ in deep."

Am. Soc. Mun. Imp. 1916 Specifications for Recut or Redressed Paving Blocks. "When the use of blocks recut from old paving blocks is permitted, such blocks must comply with the specifications for quality of stone, as required for new blocks. The dimensions may be varied, depending upon the size of the old blocks which are to be redressed, and the character of the pavement which it is sought to obtain."

Boston: "Large 'number one' blocks are to be used. The blocks are to be 3½ to 4½ in wide, 7½ to 8 in deep, and 9 to 14 in long, averaging not less than 11½ in; the edges are to be sharp and straight, forming right angles at their intersections, both horizontally and vertically; the faces are to be straight split and free from bunches and depressions exceeding ½ in and are to be laid with as close joint as possible. Special cut blocks are to be used. The blocks are to be smooth finished on the vertical sides and ends, the edges are to be sharp and straight, forming right angles at their intersections, both horizontally and vertically, and lay close with joints not to exceed ¼ in; the blocks are to be 8 to 12 in long, 4 to 4½ in wide, and 5 to 5½ in deep."

Bureau of Highways, Borough of Brooklyn, New York City: "Granite paving blocks shall be of medium grained granite showing an even distribution of constituent minerals, of uniform quality and texture, without seams, scales or discolorations showing disintegration, free from an excess of mica or feldspar and equal in every respect to the samples in the office of the Chief Engineer."

Chicago Specifications: "Upon the sand cushion shall be set granite paving blocks having a uniform grain and texture, without lamination or stratification, and free from an excess of mica or feldspar. Soft or weatherworn blocks, or those obtained from the surface of the quarry, shall not be used. The blocks shall measure from 4 to 5 in in width, 8 to 12 in in length, and 5 in in depth, and be so dressed as to have substantially rectangular, plane surfaces. Substantially rectangular is interpreted that should a block be chamfered or undercut on the side or end, the same shall be not greater than ½ in. When the blocks are in place, the surface joints shall be not less than ⅛ nor more than ⅝ in in width. Upon the application of a straight-edge to the surface of the block, the variation therefrom shall be not greater than ⅜ in. Upon the application of a straight-edge to the sides or ends of a block, the variation therefrom shall be not greater than ½ in."

Cleveland: "Paving blocks shall consist of the best quality of Medina sandstone or granite, as above specified; the Medina blocks shall not be less than 3½ nor more than 5 in thick, and not less than 6 nor more than 6½ in deep, and from 8 to 13 in long. The granite blocks shall not be less than 3½ nor more than 5 in thick, and not less than 4¾ nor more than 5¼ in deep, and not less than 8 nor more than 12 in long.

The stones to have parallel sides and ends with right-angle joints, all roughness and points of stones to be broken off, so that when set in place they shall have tight joints for a distance of at least 3½ in from the top down; the area of the bottom of any stone to be not less than three-quarters of the area of the top. Top to have a smooth, even surface."

Philadelphia: "Smooth Dressed Blocks: The blocks shall be so dressed that, after laying, a measurement of the individual joint shall show a width of not more than ½ in at the top and for a depth of 1 in, and a width of not more than 1 in in any other part of the joint. The head of the block shall be so cut that it shall not have any depressions more than ⅜ in in depth measured from a straight-edge laid in any direction across the head and held parallel to the general surface of the block. Not more than one drill hole shall show on the head of a block, and none on the ends. An average allowance of not over one block, showing drill hole on side, shall be permitted to a square yard of laid blocks.

"Rough Dressed Blocks: The blocks shall be so dressed that after laying, a measurement of the individual joint shall show an average width of ¾ in. The head of the block shall be so dressed, the surface will be rough and irregular; this irregularity on each block being not less than ¼ nor more than ⅝ in."

Rochester: "Paving blocks shall consist of the best quality of Medina sandstone free from quarry checks or cracks, and shall be quarried from fine grain live rock, showing a straight and even fracture. The material shall be of uniform quality and texture, free from seams or lines of clay or other substances which, in the opinion of the City Engineer, will be injurious to its use as paving material. Blocks shall measure not less than 3 nor more than 6 in thick, and not less than 6 nor more than 6½ in deep, and from 7 to 12 in in length. Stones to have parallel sides and ends, and right-angle joints. All roughness in joints of stone to be broken off, so that when set in place they shall have tight joints for a distance of at least 2½ in from the top down. The top to have a smooth, even surface, with no projection or depression exceeding ¼ in."

Liverpool. For heavy traffic streets, Liverpool uses setts 5 to 8 in long, 4 in wide, and 6¼ in deep. For lighter traffic streets, setts 3¼ in square on top and 5 or 6 in deep are used. These are said to give a good foothold, and are generally referred to as pegtop blocks. On still lighter traffic streets 4-in cubes have been used, but it is stated that the present tendency is for the substitution of pitch macadam for the lightest traffic.

London: "The setts to be carefully dressed and free from protuberance at the sides or on the top surface, to be closed at the joints, leaving only sufficient space for grouting to pass to the bottom."

Edinburgh: "Paving setts shall be newly quarried and obtained from the best parts of the quarry approved of, free from cracks or shakes, and square, dressed thruout in the best manner to within ¼ in of sizes."

In Glasgow, in 1913, the blocks were axed on the top, jointed on the sides and ends, and dressed on the bed, making almost a dressed dimension block. This produced an almost perfect pavement, but cost, even tho material and labor were cheap, $6.25 per sq yd.

Frankfort, Germany: "All material delivered must be hard and durable and from the best strata of quarries mentioned. It must be solid and uniform in hardness and color, and be able to withstand weather, and must contain no cracks, scales, soft spots, or foreign substance, and have no other faults. All stone that is porous, or was exposed to the sun before quarrying, shall be rejected. All stone must withstand hammering and ramming while laying without cracking. Class No. 1A and No. 1B stones for roadways must be regular in shape. The top surface must be even and smooth, rectangular and with sharp corners. The sides must be hammered smooth without hollow spots or sharp points or projections. The bottom surface must be of similar workmanship and parallel to the top surface. Class No. 2A and No. 2B stones for roadways must fulfil the general requirements of stones for Class No. 1. The top surface must be even and have sharp corners, and must not deviate from rectangular shape more than 0.2 in. The side surfaces must be so finished that when laid joints larger than 0.4 in will not ensue. The bottom surface must be parallel to the top. Class No. 3 stones: Top surface must be similar to Class No. 2, side surfaces to be so finished that joints larger than 0.6 in will not ensue; the bottom surface to be as nearly parallel to the top as possible."

Hamburg: "Stones must be of uniform structure, without cracks or foreign substance. The top surface must be even and square, and with full, sharp corners. The bottom surface must be parallel to the top, with a surface at least two-thirds the area of top. The sides must be plumb for a distance of 1.6 in from the top, and from there to the bottom as even as possible. They must not bulge so as to be the cause of large joints, nor have large cavities which would consume too much tar."

In Budapest, Hungary, when cubical blocks are used, it is specified that they shall be dressed with a diamond pointed punch with such exactness that two of them placed together will not give a joint of more than 0.44 in.

6. Cost Data on Stone Blocks

The price of granite blocks, delivered f.o.b. alongside the dock in the vicinity of New York City, depends entirely upon the cost of material, supply and demand. A fair price for the material in 1915, based on above deliveries, is $2 per sq yd for the standard blocks, and $2.30 per sq yd for the special improved blocks, dressed so as to lay with a ⅜-in joint.

CONSTRUCTION

7. Laying the Pavement

Sand Cushion. Upon the concrete base prepared for the foundation there must be spread a cushion of some material in which to bed the blocks, so that they may not only have a firm bearing, but also that there will be some little resiliency to the pavement itself. It is the general practice to make this cushion of sand. When the depth of the blocks ran from 7 to 8 in it was customary to spread 2 in of sand upon the concrete base; this would allow for the difference in the depth of the blocks and give at least 1 in under the deeper blocks. In the present practice, however, when the blocks vary in depth from 4¾ to 5¼ in, 1 in of sand is generally deemed sufficient. The specifications of the Bureau of Highways, Brooklyn, N. Y., call for 1 in of sand for Grade 1 blocks and 1½ in for Grade 2 blocks. The specifications of the Bureau of Highways, Borough of Manhattan, New York City, call for not more than 1 in and sufficient to bring the surface of the pavement when thoroly rammed to the proper grade.

In London the specifications say that the blocks shall be evenly bedded on a thin layer of sand, or other approved material, mixed with lime or cement if so directed, and spread over the concrete foundation. Liverpool requires the blocks to be set upon a bed of fine gravel ½ in thick. Glasgow calls for a sand cushion 1 in in depth, and Edinburgh for a cushion 2 in in depth.

Laying the Blocks. The practice of practically all the engineers in this country is to lay the blocks at right angles to the curb, except at intersections. A few streets have been paved by laying the courses diagonally, and theoretically it is better. While it is possible that the blocks may wear somewhat longer by this method, the extra cost of labor and the waste of material in cutting the blocks at the curb would undoubtedly more than offset the gain of wear, if any, in the pavement itself. Care should be taken by the paver, in breaking joints, to have one block lap the other as much as possible, and in any event not less than 3 in. If the blocks do not break joints by this amount, and traffic should for any reason be led into one track, practically long longitudinal joints would be formed, causing undue wear upon the blocks. Even with a scattered traffic, two or three blocks with a slight lapping of joints will soon cause an appreciable wear, where otherwise none would exist. With short blocks the joints are much more frequent, and for this reason extra care should be taken in the laying.

Blocks Laid Diagonally. In Vienna, and in parts of Hungary, however, it is customary to lay blocks diagonally on streets at an angle of 45° to the curb. The blocks are practically 7¼-in cubes, and often the blocks at the curb, and sometimes at the car tracks, are pentagons, instead of rectangles, so that no cutting or fitting of the blocks is necessary on the street. Figs. 5 and 6 show two methods of laying the blocks diagonally. It will be noticed in Fig. 5 that some of the stones are one and one-half times the length of the cubes. These stones are called binders and are set at the ends of the courses as shown. At intersections the arrangement of the blocks is different from what it is on the street proper. Where cross-walks are used they should be laid in three rows, separated by one or two courses of blocks in line with the curb. These crosswalks should be firmly bedded in sand cushions spread upon the concrete and thoroly rammed to place.

Fig. 5

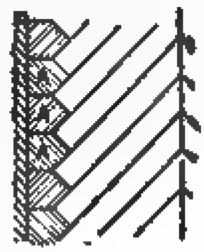

Fig. 6

Laying Blocks at Crosswalks. In the early days it was the custom to lay crosswalks with joints as shown at A, Fig. 7. Under traffic, however, the stones wore quickly along the joints, as the long joints were parallel to them. This was obviated to a certain extent by having the joints cut at an angle and laying the stones as shown in Fig. 8 at B. This was all right for traffic turning corners, as shown by the arrows, for one crosswalk, but, for the other it was as bad as before, for the traffic was parallel to

Fig. 7 Fig. 8

the joints at one of the crossings. This was finally obviated by laying the stones as shown in Fig. 9 where no traffic is parallel to the joint, whether it goes directly across the intersection or turns at the corners. The original method of laying the blocks themselves was the same as to joints as regards crosswalks, and modified in the same way, as shown in Figs. 7, 8 and 9. This latter method is what is known as the herring-bone method, and, while requiring considerable cutting at the sides, it is the best plan to date. With the improved blocks, however, and the smaller joints, the

question of joints is not quite so vital, but too much care cannot be taken to make them as short as possible in the direction of traffic. While granite block pavements have been laid in New York City for many years, still occasionally an intersection laid as shown in Fig. 7 can be seen. It of course makes no difference, as regards wear of the pavement, whether a block is 3½ or 4½ in in width, or whether two adjacent courses have this variation, but it does make a great deal of difference in the appearance of the finished pavement, and it requires very little extra care or expense to prevent it.

Fig. 9

Joints Between Blocks. The question of the width of joints between the blocks is important, and how it shall be solved depends both upon the care and skill of the paver and how well the blocks have been cut. The size of the joint must be regulated according to the kind of filler to be used. If it is proposed to fill the joints with any form of bituminous cement, the blocks cannot be laid too closely; if, however, the joints are to be filled with tar and gravel, as a variation of 1 in is allowed in the width of the blocks, great care must be taken in their selection when the courses are being laid. The Borough of Manhattan, New York City, specifies that the contractor, before he begins work, must notify the Engineer of the width of blocks he will use. This means that the blocks must be selected as to width in the quarry before they are shipped. The joints must be of a size to receive the gravel required by the specifications. If a Portland cement filler is used, the blocks should be set stone to stone, but it is not necessary that the sides be smooth and even.

The Bureau of Highways of Manhattan, New York City, specifies that the blocks shall be laid with a ⅜-in joint, while the Bureau of Highways of Brooklyn requires a ½-in joint.

Chicago: "The blocks shall be laid in contact with each other and in uniform courses across the roadway between the curbs, except at the intersections of the streets, where they shall be laid at an angle of 45° with the center line thereof. Each course shall consist of blocks of the same width, and shall be so laid that all longitudinal joints will be broken by a lap of at least 3 in. Hot dry gravel free from loam and dirt shall be swept into the interstices, and the blocks rammed with a 75-lb rammer to a true surface and a firm bed. No cracked or chipped blocks shall remain in the pavement. When directed by the Engineer the space between the granite blocks and the curb or curb wall shall be filled with a mortar composed of one part of Portland cement and three parts of torpedo sand or limestone screenings. The price bid per square yard for pavement must include all cost of this work."

Cleveland: "Stones are to be set tight together, in uniform rows, breaking joints at least 2 in and resting against stones, in the same and adjoining courses; those of the same class and thickness to be placed together in the same row; rows of similar thickness to be placed together, and set directly upon the earth foundation; no gravel or sand to be placed on top or between as stones are laid. Stones to be set perpendicular to the grade, and in right angle courses across the street, except at street and alley intersections, where the courses are to be set at such angle as the Engineer shall direct. The pavement shall always be laid by the paver standing upon the upper

side of his work; the pavement shall then be subjected to the following treatment by the Contractor, and in such order and to such extent as the Engineer shall direct. The pavement shall be laid to the proper grade and crown of the street by using cords or lines stretched lengthwise of the street and drawn tightly over and touching the top of bed stones set in the ballast, in the usual manner, as directed; these bed stones to be set in rows lengthwise of the street. Stones shall be set from 4 to 6 ft apart each way, as directed, with their tops at the proper grade and crown from the pavement. The lines or cords, when in use, shall always be kept taut and shall extend over not less than three bed stones at a time, or from paving that is laid over not less than two bed stones, making always the three points of support. In placing paving material in the beds in advance of paving, care shall be taken not to disturb the lines nor bed stones when set, both of which shall always be kept uncovered and free; and all paving shall be laid to lines set as here specified."

Boston: "Upon the concrete or gravel base is to be spread a layer of clean, coarse-screened bedding sand, and in this sand the blocks are to be laid in courses of uniform width and depth at right angles with the line of the street, unless otherwise directed by the Commissioner, with close joints, the longitudinal joints broken by a lap of at least 2 in, sufficient sand being used to bring the blocks to the grade and form for the finished roadway after they have been thoroly rammed as hereinafter provided; they are then to be covered and the covering raked and swept until the joints of the blocks are filled therewith; the blocks are then to be thoroly rammed to a firm, unyielding bed, their surface parallel to the grade and crown required, and are then to be again covered and the covering raked or swept as aforesaid; the blocks are then to be again rammed until they are solid and secure at the grade and crown of the finished roadway; no ramming is to be done within 15 ft of the face of the paving that is being laid, and in doing the ramming one rammer is to be employed to every one paver."

Manchester, England, requires that the joints shall be ½ in in width, and those of London that the blocks shall be close at the joints, leaving only sufficient space for grouting to pass to the bottom.

Principles of Joint Filling. The proper filling for joints in a stone pavement is a question that has been discussed for many years and there is much variation in the practice of the engineers in this regard. The objects sought by the filling are: To obtain a waterproof surface, to keep the blocks stable, and to preserve the joints in such a way that they will not be unduly worn under traffic. It, too, has much to do as regards the noise of a pavement, and as the principal objection to stone pavement is its noisy quality, joint filling on this account alone is particularly important. The joint should be waterproof so as to prevent moisture getting down below the blocks and displacing the cushion. It is a serious question whether it is advisable to have a pavement as nearly masonry as possible. This might be true from a wear standpoint alone, but as has been said before, noise is a great objection to stone pavement, and if the pavement be practically monolithic the noise will be very great. The different joint fillers used in the United States are: Sand; gravel, with its interstices filled with pitch; cement grout; or some bituminous compound.

Steele (22) states: "The aim should be for the pavement to be as near masonry as possible, and it is useless to attempt this with the materials and method of applying them now in use. If instead of grouting the joints, the mastic was applied with a trowel during the laying of the setts, it is probable that a fairly permanent water-tight joint would be obtained; the cost of the work would undoubtedly be increased, but as the weakest part of any structure is generally at the joint, any reasonable cost to improve this would be repaid by the longer life of the finished pavement."

Sand Filler. The first granite pavements were laid on a sand base. The necessity of a waterproof joint was not recognized, and, if it had been, it would not have been easy to obtain it with any filler when the blocks were laid upon sand, as they were liable to settle unevenly under traffic and thus break the bond. Sand, therefore, was used for filling the joints.

Bituminous Fillers. The tar pitch or asphalt joint is one which, if successfully made, is very satisfactory. The blocks, however, must be so dressed that they can be laid with close joints, as, if they are large, the quantity of pitch might be so great as to allow the blocks to move in warm weather, or the pitch itself might run. Also the expense of making the joints would be too heavy. It has seemed difficult, however, to get a bituminous filler that will be perfectly satisfactory under all conditions of climate or temperature. This no doubt will be overcome as bituminous joints come into more general use. In Europe, bituminous fillers are the principal type.

Advantages of Bituminous Filler. The great objection to stone pavement is that it is noisy under traffic. Anything that can be done to reduce the noise will add very greatly to the value of granite as a paving material. If granite blocks are so dressed that they will have a joint not exceeding ¼ in, the joint can be filled with a stable bituminous material in such a way as to isolate every block from its neighbor. The noise produced on a granite pavement is caused by the action of the wheel upon the individual blocks. With a stone pavement that is practically a masonry construction, the noise caused by the wheels is transmitted from one block to another, so that soon there is not simply the noise caused by a moving vehicle at the place where it happens to be, but the accumulated noise of its trip over the pavement and the reverberations which must accordingly follow it. If, on the other hand, each block can be surrounded with a non-conductor of noise, so that there is no transmission of noise from block to block, the noise will be reduced to a very great extent, and if the blocks are smooth and they are laid so as to form an unbroken surface in the street, the noise will be still further reduced. The noise made by a vehicle passing over such a pavement would be much less than if passing over one of the old-style pavements with tar and gravel joints.

Pitch fillers came into use soon after the blocks were made of better form so that they could be laid with closer joints and thus be made more stable of themselves, and with the narrow joints they would not require an undue amount of pitch. The first pavement laid in this way was on Fourth Ave., Borough of Manhattan, New York City, between Astor Place and 23rd St., in 1910. The pitch compound was not exactly satisfactory, altho the pavement, which has been in use 7 years, is in extremely good condition and shows very clearly the advantage of this construction over the old method.

Gravel and Bituminous Filler. When the concrete base came into use, it was deemed advisable to fill the joints with gravel, the interstices of which were filled with a compound made of 100 lb of coal tar pitch, 20 lb of asphalt, and 3 lb of residuum oil. The original granite pavements on concrete were laid with a joint from ¾ to 1 in in width, so that fairly large gravel could be used, and the voids were such as to freely allow the bituminous filler to flow, so that when a sufficient quantity was used the joint would be full and water-tight. Coal tar, as is well-known, is subject to changes of temperature, so that a compound that was not brittle in winter would be soft and liable to run in summer, and for that reason the pitch was fluxed with the asphalt and the residuum oil. This method required from 3½ to 4½ gal of the compound per sq yd, and cost in New York City, in 1895, from 35 to 40 cents per sq yd when this portion of the pavement was let to a sub-contractor.

Tar and Gravel Filler. The size of the gravel in a tar and gravel joint

must be governed by the width of the joint, and as to make a joint as a whole successful, the pitch must freely percolate thru the interstices of the gravel, the size of the gravel should be fairly large. It should not be too well graded, as, even with some of the particles large, a gradation can be had that will prevent the free flow of the pitch even when hot. The success of this joint depends mainly upon having the interstices of the gravel completely filled, as without that it is very difficult to keep the joints waterproof, and this is recognized at the present time as a necessity from a sanitary standpoint if from no other. If, then, the joints are made wide enough to use large size gravel, they will wear out on the top under the constant action of the shoes of horses, and the edges of the blocks in turn will be worn and rounded off, soon making a rough and uneven street. Therefore it has not seemed that this method of construction was satisfactory. It is expensive, and the results have not seemed to justify the expense. If it be argued that the joints can be made smaller, which is true, it would be necessary to have the size of the gravel smaller, and thus increase the difficulty of making the joint waterproof. It would seem, therefore, that if the joints are to be reduced, a little more care should be exercised in the manufacture of the blocks and the joints made so small that they could be filled with a bituminous compound, either alone or mixed with sand. It is probable that the practice of filling the joints with tar and gravel will shortly be almost entirely discontinued in first-class stone pavements.

Pitch and Sand Filler. A method following the English practice has been adopted of mixing fine sand with the pitch in order to make it tougher and overcome its tendency to become brittle in cold weather. This has not been in use in this country long enough for an intelligent estimate of its value to be formed, altho everything seems to indicate that it will be successful.

Portland Cement Grout was probably first used in this country for a joint filler in Worcester, Mass., about 1900. The practice then was, after the blocks had been rammed, to fill the joints with fine broken stone and then flush them with a grout formed of one part Portland cement and two parts sand. This was allowed to set a week or 10 days before the street was opened to traffic, and this practice has been followed in that city to a great extent since that time. The pavements so laid are smooth, and, if the joints hold good, wear evenly and are generally satisfactory. This class of filler has been used to quite an extent in Europe, but only in a small way in this country. One great advantage is that, on account of the fluidity of the grout when mixed and its hardness and durability after having set, the joints between the blocks can be comparatively large and the blocks themselves rougher on the sides, as the grout will flow freely in and around bunches and when set makes the whole joint solid and complete. It, too, forms what was referred to in English reports as masonry construction, and, when the joint holds, it probably makes as durable a stone pavement as can be laid.

Disadvantages of Cement Grout Fillers. As the joints are absolutely filled with a hard substance, the surface of the pavement becomes very smooth under traffic, and thus slippery for horses. Pavement, however, thus laid, keeps its form, and for that reason presents a light resistance to traffic. It has, however, several material objections. After being grouted in this manner the pavement must be kept free from traffic from 10 days to 2 weeks, according to the weather, in order to allow the grout to become

thoroly set. This is absolutely necessary, for, if traffic is allowed on the street too soon, the blocks are shaken, the partial set is destroyed, and the joints become little better than if filled with sand. In smaller cities and on minor streets this may not be a serious objection, but in large cities on important streets it is prohibitive. It is also difficult to apply the grout in such a way as to get uniform results over the entire pavement surface. On cement grouted streets, areas 10 or 15 ft square are often seen where the grout has entirely disintegrated, altho the rest of the pavement is in perfect condition. This may be due to the unequal mixing of the sand and the cement, or to the possibility of the sand and the cement being segregated in the process of application. This difficulty, however, will undoubtedly be overcome if cement grout joints come into general use. Another objection is the difficulty of making openings in a cement grouted pavement and repairing it afterwards. It may be said that this is not a legitimate objection, but it must be admitted that, however objectionable they may be, frequent openings must be made in the streets of American cities, and that, if any street pavement cannot be readily and well repaired, it will be used to a limited extent. It is not only expensive to make openings thru the pavement, but a great many blocks are broken and destroyed, and so must be replaced with new. The blocks taken up, even if not broken, are coated with the cement and must be cleaned before being used again. It may be said that this extra cost is not borne by the city, but by the parties who make the openings. This may be true, but the expense is borne by someone, and it must come from the pockets of the property owner either in direct payment to the party who makes the openings or in a reduction of dividends or returns on his investment if the openings are made by corporations. These openings are replaced with difficulty because it is almost impossible in this country to keep traffic from a repaved trench long enough to allow the cement grout to set. It may be argued that this should not be, but as a matter of fact it is, and a different result cannot be easily obtained.

American Methods of Filling Joints. The specifications for joint filling adopted in 1916 by the Am. Soc. Mun. Imp. are included in Art. 9.

The Borough of Brooklyn, New York City, has laid some stone pavements with grouted joints, and in 1915 provided specifications for a cement grout filler, a tar and gravel filler, a refined asphalt joint filler, and a filler composed of coal tar pitch and hot dry sand mixed in the proportion of 1 : 1. The specifications used by the Bureau of Highways for the different fillers enumerated do not vary materially from those herein given.

The Bureau of Highways, Borough of Manhattan, New York City, provided in 1914 for a bituminous joint filler as follows:

"The joint filler used shall be a mixture of paving cement, described hereafter, and hot, dry sand in the proportion of one part sand to one part paving cement by volume, or as much sand up to that proportion as the paving cement will carry. The sand shall be clean and sharp and all of it shall pass a 10-mesh screen. It shall be thoroly mixed with the paving cement by stirring or otherwise. The mixture shall be poured into the joints until they are full and remain full, repouring being done if necessary so that they shall remain permanently filled flush with the surface of the pavement.

"The coal tar paving cement shall be a straight run residue obtained from the distillation of coal tar and shall comply with the following requirements:

1. Melting point shall be not lower than 43° C (110° F) nor higher than 52° C (125° F).
2. Free carbon shall not be less than 20 nor more than 35%.
3. Specific gravity at 25° C (77° F) shall not be less than 1.22 nor more than 1.30.
4. Specific gravity of the distillate to 354° C (670° F) shall not be less than 1.06 at 60° C (140° F) compared with water at the same temperature.

"The Contractor before beginning work on any contract shall obtain from the Engineer a statement in writing as to the melting points desired for that particular contract and a variation of 2.8° C (5° F) either way will be permitted from this melting point, but within the limits as indicated above. The kettles in which the coal tar paving cement is heated on the street shall be equipped with approved thermometers and the paving cement shall be heated to a temperature of not less than 121° C (250° F) nor more than 149° C (300° F) and shall be poured when between these limits.

"The asphaltic paving cement shall be obtained by the distillation of an asphaltic petroleum at a temperature not exceeding 700° C (1292° F), and shall comply with the following requirements:

1. It shall be homogeneous.
2. Melting point shall not be less than 54° C (130° F) nor more than 63° C (145° F).
3. Solubility in carbon tetrachloride shall not be less than 98.5%.
4. Penetration at 25° C (77° F) shall not be less than 60 nor more than 100, the penetration test being made with a No. 2 needle for 5 sec under a load of 100 g, and the penetration at 38° C (100° F) shall not exceed three times its penetration at 25° C (77° F), the condition of time and load being as above established. The Contractor before beginning work shall obtain from the Engineer a statement in writing as to the penetration desired for any particular contract and a variation of not greater than ten points either way from this penetration will be permitted.
5. Ductility at 25° C (77° F) shall not be less than 40 cm at the penetration called for.
6. It shall not lose more than 3% by volatilization when maintained at a temperature of 163° C (325° F) for 5 hr, nor shall the penetration of the residue, after such heating, be less than one-half the original penetration."

Chicago: "After ramming, the spaces between the blocks are to be completely filled with a paving pitch which shall conform to the following requirements:

1. It must be obtained from coal tar only and there must be no admixture with it of any material not obtained from coal tar.
2. Its specific gravity at 25° C (77° F) shall be not less than 1.17, nor more than 1.30.
3. It shall contain not less than 22 nor more than 37% of free carbon, the free carbon being defined as the organic material insoluble in cold carbon disulphide after digesting 12 hr at room temperature.
4. On heating 100 g of the pitch to 315° C (600° F), the distillate shall not exceed 8% by weight. The distillation shall be conducted in an 8-oz asbestos jacketed retort, in which is inserted a 3-in immersion thermometer, the bottom of which extends to within ½ in of the surface of the pitch when in a fluid state, and the temperature increased at the rate of 11° C (20° F) per min until the first drop of distillate is formed, and thereafter at approximately the rate of 1 drop per sec. The total length between the thermometer entering the retort and the end of the adaptor shall be 22 in. Two sheets of wire gauze each 20-mesh fine are placed between the bottom of the retort and the burner.
5. The melting point of the pitch shall be not less than 54° C (130° F) and not more than 60° C (140° F) when obtained by the following method: Five grams of the pitch are molded by hand into the approximate form of a cube. Thru the center of this cube is inserted a Brown & Sharpe gauge bent copper wire, 0.08 in in diameter, from face to face of the cube. The bottom of the cube of pitch and the bulb of the thermometer are placed 1 in above the bottom of a 250 cu cm Griffin form beaker filled with 200 cu cm of water and kept at a temperature of 21° C (70° F) for 15 min. The temperature is then raised 5° C (9° F) per min, until the softening pitch touches the bottom of the vessel, or a tin cover, or paper, or sand, placed therein to catch the melted pitch. The temperature recorded at the instant the pitch touches the bottom is the melting point of the pitch.
6. The penetration of the pitch shall be not less than 75 and not more than 110 as determined by the New York Testing Laboratory Penetrometer. The sample shall be placed in water which is maintained at 38° C (100° F) for not less than 30 min. The penetration shall be taken under water at 38° C (100° F) under a weight of 50 g acting for 5 sec.

"The pitch must be used at a temperature of not less than 149° C (300° F) and not more than 177° C (350° F) and be spread in sections if the Engineer so directs. All joints and edges of the block shall be completely filled with pitch and if, after cooling, the joints are not flush and even with the surface, they should be repoured.

"The Contractor shall provide the Board of Local Improvements with a duplicate delivery ticket for each and every load or tank of paving pitch delivered on the work. This ticket must be signed by the consignor and be of a form approved by the Board of Local Improvements.

"Immediately after the spreading of the paving pitch, and while it is still hot, the blocks shall be covered to a depth of not less than 1/4 in with hot roofing gravel. This gravel must be entirely free from sand or loam, and not exceed 1/2 in in size. All gravel must be clean, washed, dried and heated enough to prevent the chilling of the pitch. The tarring and top dressing must be completed each day to within 5 ft of the face of the blocking."

Cleveland: "Mastic Filler. The mastic joint filler shall consist of a mixture of paving pitch, of a quality hereinafter described, and hot, dry sand, of fineness hereinafter specified, in the proportion of one part pitch and one part sand by volume. The paving pitch shall be a straight run residue obtained from the distillation of coal tar. It shall have a melting point of not less than 43° C (110° F) or more than 49° C (120° F) by the cube method of testing, and shall have a free carbon content of not less than 20 nor more than 35%. The sand shall be fine, clean and moderately sharp lake sand of approved quality; not more than 6% shall pass a 200-mesh sieve and not more than 20% shall be retained on a 40-mesh sieve. The sand shall be thoroly mixed with the paving pitch, either by hand stirring or by a mixing machine of approved construction. At the time of mixing, the sand shall be heated to a temperature of not less than 177° C (350° F) and the pitch shall be heated to a temperature of not less than 93° C (200° F) nor more than 121° C (250° F). After thoroly mixing, the filler shall be poured into the joints to the full depth thereof, repouring until all joints are filled flush with the surface of the pavement. Extra care shall be used at the gutters and around manholes, etc, to effectually prevent leakage of water into the sub-roadway. At the discretion of the Engineer the filler may be flushed into the joints by means of approved squeegees or push brooms. In this event the joints shall be flushed full, the same as where poured. A top dressing of clean, coarse sand shall be spread over the pavement immediately after the filler is applied and while it is still soft and pliable.

"Coal Tar Paving Pitch Filler. The joints or spaces between the bricks or stones and those between the bricks or stones and the curb, railway tracks, around manholes, etc, shall be filled with coal tar pitch, which shall comply with the following requirements: Physical Properties. When in place in the pavement it shall be of such a character that it will adhere firmly to the paving brick or stone and to the curb, and shall be sufficiently plastic to allow for contraction and expansion in the pavement without developing cracks in the joints. It shall be proof against action by water and all acids and alkalis to which the pavement may be exposed. The filler shall be such that it retains its consistency under extreme temperature. The free carbon shall not be less than 25 nor more than 40%. The specific gravity shall not be less than 1.23 nor more than 1.30 at 15.5° C (60° F). It shall have a melting point varying not more than 2.8° from 57° C (5° from 135° F) determined by the cube method.

"Methods of use. The filler shall be heated and poured into the joints to the full depth thereof, at a temperature of not less than 149° C (300° F), nor greater than 177° C (350° F). All joints shall be completely filled to the top. The top dressing of sand shall be spread over the pavement immediately after the filler is applied and while it is still soft. In cold weather the sand shall be heated so as to readily bond with the pitch. Extra care shall be used at the gutters and around catch-basins, etc, to effectually prevent the leakage of water into the sub-roadway.

"Asphalt Filler. The interstices of the brick or stone blocks shall be completely filled with an asphalt filler heated to a temperature of not less than 177° C (350° F) nor more than 232° C (450° F). This asphalt filler shall not contain pitch nor any part of coal tar. It shall contain at least 98% of bitumen soluble in carbon disulphide. It shall remain pliable at all temperatures to which it may be subjected as a street paving filler; it shall be absolutely proof against water and street liquids; it shall firmly adhere to the brick or stone and be pliable rather than rigid. The penetration, with a No. 2 needle, shall conform to the following: 100 g, 5 sec at 25° C (77° F) 25 to 60; 200 g, 1 min at 0° C (32° F) not below 25; 50 g, 5 sec at 46° C (115° F) not above 110. Care should be exercised to completely fill all openings around street structures, and the street shall not be used for traffic until the filler is com-

pletely set. A top dressing of sand shall be spread immediately after the filler is applied and while it is still soft."

Boston: "WITH GRAVEL JOINTS. If the blocks are to be laid with gravel joints, the blocks after being rammed, as aforesaid, are to be covered with clean, coarse-screened sand, thoroly dried by artificial heat if necessary, and the sand is to be raked or swept until the joints are filled therewith; the entire area is then to be covered with a layer of the same sand at least 1 in thick.

"WITH PITCH JOINTS. If the blocks are to be laid with pitch joints, they are to be laid as above, but the covering is to be washed pebbles, equal in quality to the best Long Island white pebbles, that will pass thru a ¾-in screen and will not pass thru a ⅜-in screen when number one blocks are used. If special-cut blocks are used the openings are to be ⅝ and ¼ in respectively. They are to be thoroly heated and raked or swept and the blocks are to be thoroly rammed as aforesaid, and the joints filled with pebbles to within 1 in of the surface; the joints are then to be filled with a paving cement of proper consistency until they will receive no more and are filled flush to the grade and crown of the finished roadway; any cement left upon the top of the blocks is to be covered with dry sand, sufficient to absorb the cement, if so required by the Commissioner; the paving cement is to be obtained by the direct distillation of coal tar and is to be kept at a temperature of 149° C (300° F) while being used.

"WITH GROUT JOINTS. If the blocks are to be laid with grout joints, they are to be laid, covered and rammed as provided for pitch joints and then the joints are to be filled as provided for the pitch joints, but with grout which is to consist by measure, of one part of Portland cement to one part of clean, sharp and fine sand; the cement and sand just before the grout is to be used to be thoroly mixed dry in a manner approved by the Commissioner; enough water is then to be added and the grout thoroly worked with hoes or other tools to the proper consistency."

Philadelphia: "GROUT JOINT FILLER: Immediately after the blocks are laid, sufficient gravel shall be spread over the surface and swept into the joints so as to fill the space between the blocks to a depth of about 2 in from the bottom. The blocks shall then be rammed to thoroly settle and compact this layer of gravel in the joints, and so as to leave no blocks above or below the general surface of the finished pavement. After the blocks have been brought to a uniform surface, grout filler, composed of one part of Portland cement and one and one-half parts of clean, sharp sand mixed with clean, fresh water in such quantity as in the opinion of the Chief of the Bureau is necessary to give the proper consistency, shall be poured into the joints until filled and surplus grout appears on the surface. The grout shall be broomed into the joints, if necessary to fill them, and the operation shall be continued as the grout settles, until the joints are thoroly filled flush with the surface of the blocks, immediately after which the entire pavement shall be broomed to a smooth surface, sufficient grout being applied to bring the surface even with the highest part of any of the blocks. The blocks shall be wetted by sprinkling with water immediately before applying the grout, if dry or heated atmospheric conditions require this precaution to be taken. A squeegee scraper shall be used on the last application of the grout. Within ½ to ¾ hr after the last application has been made and the grout between the joints has fully subsided and the initial set is taking place, the whole surface shall be lightly sprinkled with water and the surplus grout left on the top shall be swept into the joints, bringing them up flush and full. After the grouting is done and a sufficient time for initial set has elapsed, so that a coating of sand will not absorb any moisture from the grout, ½ in of sand shall be spread over the whole surface. When the work is subjected to an air temperature of 24° C (75° F) or more, the sand shall be sprinkled three times a day for 3 days. The highway shall be kept closed to traffic for at least 10 days. Should the bond between the blocks become broken, the joints shall be cleaned out, even if it is necessary to take up and relay the blocks. The part so taken up and relaid shall be regrouted and protected until hardened.

"BITUMINOUS JOINT FILLER, SPECIFICATION A: Immediately after the blocks are laid, sufficient coarse hot gravel shall be spread over the surface and swept into the joints so as to fill the space between the blocks to a depth of about 2 in from the bottom. The blocks shall then be rammed to thoroly settle and compact the first layer of gravel in the joints and so as to leave no blocks above or below the general surface of the finished pavement. The joints shall then be poured one-half full with pitch

filler as herein described and then filled to within ½ in of the surface with hot gravel and again poured with the filler. This last pouring shall bring the filling flush with the tops of the blocks at the joints. The final pouring of the filler shall be immediately followed with a sufficient amount of hot gravel, applied at the joints, to conceal the filler. The gravel shall be clean, washed gravel between ⅛ and ⅜ in in its largest dimension, not over 25% of which shall be of the ⅜- in size. The filler shall comply with the following test requirements: (1) Specific gravity: It shall have a specific gravity between 1.23 and 1.33 at 15.5° C (60° F). (2) Melting Point: It shall have a melting point between 49° and 54° C (120° and 130° F). (3) Free Carbon: It shall contain between 20 and 30% of free carbon. The pitch filler as used on the work shall have a temperature of not less than 121° C (250° F), and shall at no time be heated above 163° C (325° F). In applying the gravel and pitch, care shall be taken that the block laying is closely followed by the filling, and in no case shall the pavement be left over night, or when work is stopped, without the filler being completed. In case of rain stopping the filling operation before it is finished, the joints shall be protected by the use of waterproof canvas or other means so as to exclude moisture or water, and, under no circumstances, shall the filler be poured into wet joints.

"Bituminous Joint Filler, Specification B: Immediately after the blocks are laid, sufficient coarse, hot gravel shall be spread over the surface and swept into the joints so as to fill the space between the blocks to a depth of about 2 in from the bottom. The blocks shall be rammed to thoroly settle and compact the first layer of gravel in the joints and so as to leave no blocks above or below the general surface of the finished pavement. The joints shall then be poured one-half full with a bituminous filler as hereinafter described, and then filled to within ½ in of the surface with hot gravel and again poured with the filler; this last pouring shall be flush with the surface of the blocks at the joints. This final pouring of the filler shall be immediately followed with a sufficient amount of hot gravel applied at the joints to cover the filler. The gravel shall be clean, washed gravel, between ⅛ and ⅜ in in its largest dimension, not over 25% of which shall be of the ⅜-in size. The asphalt filler to be used in filling the joints between and around the paving blocks shal. be a bituminous material, either natural or artificial, entirely free from coal tar, or any product of coal tar distillation. It shall be waterproof, free from water or decomposition products, shall adhere firmly to the paving stones, and shall remain ductile and pliable at all climatic temperatures to which it may be subjected in actual use, and shall not run in the joints in the hottest temperature of summer, nor become hard or brittle thru the action of frost. The asphalt filler shall conform with the following requirements:

1. Solubility: It shall contain not less than 98% pure bitumen soluble in carbon disulphide. Of the total amount soluble in carbon disulphide, 98.5% shall be soluble in carbon tetrachloride.

2. Penetration: When tested by the Dow method with a No. 2 needle weighted with 200 g and operating for 1 min at 0° C (32° F), it shall have a penetration greater than 25. When tested with a No. 2 needle weighted with 50 g and operating for 5 sec at 46° C (115° F), it shall have a penetration not greater than 110. When tested with a No. 2 needle, weighted with 100 g and operating for 5 sec at 25° C (77° F), it shall have a penetration between the limits of from 25 to 60.

3. Viscosity: One-half gram of the material when made into a ball shall not melt and drip thru an aperture 1 mm in diameter at less than 93° C (200° F)."

Rochester: "If a paving pitch filler is used, the joints shall be filled with clean, dry, hot gravel of proper size as herein specified, heated in pans especially provided for that purpose, and poured from cans having small spouts and thoroly settled in place with wire picks until the level of the gravel is at least 2 in below the top of the pavement. The gravel used between the blocks shall be of such size as will pass thru a sieve having 4 meshes per sq in, and be retained on a sieve of 64 meshes per sq in, and must be screened when dry."

European Methods of Filling Joints.

Manchester, England: "The joints to be filled with ⅜-in chippings of limestone or other approved stone, and to be flushed with a preparation of pitch and tar of approved quality thoroly boiled, and mixed in proportions satisfactory to the Surveyor; the pavement to be lightly covered with paving chippings."

London: "The stones to be well rammed and back rammed, at the option and as

directed by the Engineer, to a uniform surface, and jointed with a bitumen composed of tar, pitch and creosote in approved proportions, and as the work proceeds to be well flushed with sharp Thames sand and cement or lime, as may be directed, in the proportion of 5 to 1, and coated if so directed, with fine hoggin. If the Engineer shall so direct, the bitumen shall be omitted and the setts entirely grouted up with three to one cement grout."

Liverpool: "The joints shall then be carefully grouted until perfectly filled with a hot composition consisting of coal pitch and creosote oil, and finally the pavement shall be covered with ½ in of sharp gravel.

"Special Coal Tar Pitch. The pitch shall yield no matter volatile below 270° C (518° F) when subjected to dry distillation, and its total volatile organic matter shall not fall below 30%. It shall not contain more than 80% of its weight of matter insoluble in petroleum spirit of 0.700 specific gravity (boiling) and must be free from extraneous matter, such as sand and grit. It must twist fairly after immersion for 2 min in water at 60° C (140° F), but not under 55° C (131° F).

"Special Creosote Oil. The oil supplied shall be obtained exclusively by the distillation of coal tar, and shall not contain any portion of the distillate obtained below 240° C (464° F). None of it shall re-distill below 240° C (464° F). The oil as obtained by distillation of coal tar shall not be treated in any way, either by the addition of any coal tar product, or by the extraction of any of its constituents, excepting such extraction as may be necessary to comply with the following clause. It shall contain no moisture. It shall contain no solid matter at 15.5° C (60° F) and shall have a specific gravity of not less than 1.075 taking water as 1.00 at 15.5° C (60° F). It shall contain not less than 40% of its constituents that do not distill over below 320° C (608° F) and the 60% which does distill over below 320° C (608° F) shall contain 10% of tar acids, to be extracted by soda, specific gravity 1.125 (water 1.00)."

The Edinburgh specifications state that the joints shall be filled flush with boiling hot pitch, prepared and tempered with creosote oil, and the specifications for the same are as follows: "The asphalte for grouting causeway joints shall be composed of best quality pitch and creosote oil, boiled together in proportions of about 1000 lb pitch to 15 gal oil. The pitch shall be free from grit or sand, but shall contain a sufficient proportion of heavy non-volatile oils. The creosote oil shall be obtained only from coal tar, and be of at least 1.060 specific gravity, at 15.5° C (60° F). The mixture shall be tempered so that, when boiled, and cooled in water to 15.5° C (60° F), it shall be capable of stretching out to fine threads, at least 36 in long, before rupture; and, with a detached 3 ft length, be capable of striking a hard blow on any smooth surface without cracking."

Glasgow, which awards contracts for 3 years and furnishes the blocks, provides that the paving shall be well grouted with cement or pitch grout, as directed, and shall then be covered with sand ¼ in in depth. The following are the requirements for the pitch and cement grout. Pitch grout shall consist of pitch and oil made from pure coal tar, manufactured in gas-works by the destructive distillation of coal in close retorts. No blast furnace, iron-works, or coke-oven pitch or oil will be allowed to be used. The oil shall be of a specific gravity of from 1.032 to 1.050 at 15.5° C (60° F). The flash test shall not be under 47° C (116° F). Sufficient oil shall be used to produce a plastic grout. The grout shall be boiling hot when used. The Contractor shall intimate to the Master of Works the names of the persons from whom the pitch and oil are to be obtained. The pitch boilers shall be so constructed that the vapors from the boiling material shall be conveyed into the furnace, which shall be fired with the best coke. No coal shall be used. When the Master of Works considers it necessary, crushed granite shall be used for partly filling in the joints of the setts. The granite must be kiln-dried, and then passed over a riddle of ¼-in mesh to remove all sand and dust, and shall be laid in the joints in two layers. Previous to the granite being put between the joints, pitch shall be run in to the depth of 1 in, the first layer of granite shall then be put in, and be thoroly grouted with pitch; the second layer of granite shall then be put in to fill the joints level with the surface, and be also thoroly grouted. One ton of crushed granite shall do not less than 240 sq yd."

In certain cities of Great Britain, where the character of stone block work was reported to the Third Int. Road Congs. London, 1913, the following fillers were used:

Aberdeen, mixture of pitch and tar; **Bradford**, pitch; **Sheffield**, mixture of pitch and tar, or cement mortar.

Inspection. The inspector who has charge of the construction of a stone block pavement must watch carefully to see, not only that the requirements of the specifications are carried out, but must watch in detail the workmen so that the little things, which often add so much to the general result, will be well done. For instance, it is extremely necessary that the ramming be carried on carefully and the blocks firmly bedded in such a way as to leave the surface true and even, so that when heavy traffic comes upon the blocks, individual blocks will not be depressed below those adjacent and thus deform the surface. Special care should be given to the joints when the blocks are laid, as after they are rammed and trued up, the width of the joints always is larger than before, probably due to the fact that the blocks are not always set vertically by the paver himself. No matter what filler is used, the joints should be made absolutely full, and preferably as nearly that as possible at the first pouring. If bituminous cement is used, it is poured hot; and if it is allowed to cool and soak away, leaving voids, it is not always possible to fill the joints completely, or to know even if they have been filled. With a Portland cement filler, some specifications require that the blocks shall be entirely covered with the grouting to a specified depth. This seems unnecessary, as the grouting will wear off unevenly, making the surface of the pavement rough, and not adding materially to its life. When a Portland cement filler is used it is of the greatest importance that all traffic should be kept off the pavement until the cement has thoroly set.

8. Recut Blocks

Description. For many years the granite blocks taken from a street when a new pavement was to be laid were not considered to be of any particular value for use in city streets; they were sold for use in freight terminals and similar locations where a first-class pavement was not required. About 1908, however, some of the granite block producers of New York City took up the question of recutting the old blocks and laying them in a new pavement. These old blocks were from 7 to 8 in in depth, and some of them 14 in long. The idea was to break them in two, in the center, and to use the new face as the head of the block. This would give a block from 5 to 6 in deep, if the original blocks were 10 and 12 in long. If necessary, the old head of the block could be dressed so that it would have a very good shape. In order to get the best results from work of this character a little more variation must be allowed in the specifications, and that is permissible, as generally this work is done on streets of light traffic. Success, too, depends to a great extent upon the character of the granite in the old blocks, as some will break much more easily than others. It is undoubtedly true, with the idea of the smaller granite blocks, that a great many of the old blocks can be utilized, and if recut as before described and laid on streets of moderate traffic, excellent results can be obtained.

The Bureau of Highways, Brooklyn, N. Y., has laid a considerable quantity of this pavement, and with satisfactory results; and the specifications for this pavement are as follows: "When the use of blocks recut from old granite blocks is permitted under the contract, such blocks shall comply with the specifications for quality as required for new blocks, and be of the following dimensions, not less than 6 nor more than 10 in long on top, not less than 3¼ nor more than 4½ in wide on top, and not less than 4¾ nor more than 5¼ in deep. The recut blocks shall be dressed in the manner specified for new blocks, except that the sides and ends shall be sufficiently smooth to permit of the blocks being laid with joints not exceeding ⅜ in in width

at the top and for 1 in downward therefrom, and not exceeding 1 in at any other part of the joint."

Borough of Manhattan, New York City. A contract was carried out in the Borough of Manhattan, in 1914, amounting to something over 5000 sq yd of recut blocks, the blocks being broken in two and laid with the newly broken side up, on a 1-in sand cushion. A portion of this pavement was filled with tar and another portion with cement grout, the object being to ascertain the difference in wear of the two methods. This pavement cost $1.45 per sq yd, not including the foundation.

Borough of the Bronx, New York City. Probably the first street laid of recut blocks was in the Borough of the Bronx in 1909. The specifications called for the blocks to be 6 to 12 in long, 3½ to 4½ in wide, and 5½ to 6½ in deep, and, as the work as a whole was an experiment to a certain extent, blocks 4¾ or even 5 in in width were used provided all courses were of the same width. The price bid for the work was $1.25 per sq yd for the granite laid. The joints were filled with cement grout, so that all the small inequalities of the blocks were filled. The result was a first-class pavement for light traffic streets and at a very small price. The contractor was paid, for making the blocks, $10 per thousand.

Philadelphia. More recently, a street in Philadelphia, containing over 10 000 sq yd, was laid of blocks reclipped at a cost, including the sand cushion, of $1.48 per sq yd, the old concrete being used. The specifications called for the blocks to be redressed, of dimensions 5 to 6 in deep, 5 to 7 in long, and 3½ to 5 in wide.

In Troy, N. Y., in 1913, a pavement of old blocks was relaid, but cut by a little different method. The blocks were practically of regulation size, and were first halved, and then quartered, so that they were from 7 to 9 in long, 4 to 5 in wide, and 4 to 5 in deep. These blocks were laid on a sand cushion, and grouted with Portland cement. The cost was $2.30 per sq yd including foundation, with maintenance for a period of 5 years. In this work it is stated that an excess of 25% of blocks was obtained over and above what was required for the street itself, and that the contractor was allowed $15 per thousand for them delivered within a radius of ½ mile from the place of cutting. The price for the standard pavements in Troy had been on an average $3.85 per sq yd.

The City of Newark, N. J., has probably laid more of this pavement than any other city. In 1914 it let contracts for 32 500 sq yd of recut blocks, with grouted joints, at an average cost of $2.50 per sq yd. In 1914, Howell (15) stated that the old blocks there ran from 10 to 14 in in length; that a block maker in a day of 8 hr could cut 175 blocks, making 350 small ones, and that the city sold the contractor the old blocks at $30 per thousand, which would make the smaller ones cost him $15 per thousand, including the cutting. The blocks ran 21 to the yard for the large size and 42 to the yard for the small size.

9. Specifications for Construction

The following specifications were adopted in 1916 by the Am. Soc. Mun. Imp. For sections covering physical properties of stone blocks see Art. 5. Specifications relative to the practice in several American and European cities pertaining to methods and materials employed in filling joints in stone block pavements will be found in Art. 7.

"**Sub-Foundation.** Any soft or spongy material below the subgrade, shall be replaced with sand, gravel or other material, as directed by the engineer, and thoroly rammed or rolled. When such extra fill exceeds 5 cu yd, payment will be made for the excess. Care shall be taken in excavating not to disturb the sub-foundation, except where necessary to remove the soft or spongy materials. The entire sub-foundation shall be compact and hard, and the contractor shall be required to ram or roll it thoroly with a roller satisfactory to the engineer.

"**Cement-Concrete Foundation.** After the sub-foundation has been prepared to the satisfaction of the engineer, a concrete foundation 6 in thick shall be laid thereon. The concrete shall conform to the Am. Soc. Mun. Imp. specifications for concrete for pavement foundation. The grading and sub-foundation shall be completed at least 50 ft in advance of the laying of concrete.

"**Cushion Course.** On the concrete base shall be spread a layer, averaging 1 in in

depth, of clean, coarse, dry sand, free from all gravel exceeding ¼ in in size. Upon this sand bed the blocks shall be laid in courses at right angles to the line of the street, and in a straight line from curb to curb, except in special cases, when they shall be laid at such an angle as may be directed by the engineer. The blocks shall be laid as closely as possible, each block touching the adjoining one on sides and ends, and in courses of uniform width. All joints shall be broken with a lap of at least 3 in. The blocks shall not be laid more than 25 ft in advance of the ramming.

"Ramming. After the blocks are laid, they shall be rammed to a solid bearing; the joints shall be adjusted; all unsatisfactory blocks shall be taken out with tongs, and all low blocks shall be raised by adding to the bed. The whole pavement shall then be rammed to an even and true surface. Pinch bars shall not be used except by special permission of the engineer and no sand shall be placed in the joint except when mixed with the bituminous filler specified hereafter.

"Filling Joints. The following specifications A, B, or C, shall govern the use of Tar Pitch (A), Asphalt (B), or Cement Grout (C), depending upon the kind of filler to be used in the joints.

"A. Tar Pitch Filler. The joint filler used shall be the paving pitch hereafter described thoroly mixed with as much hot, dry sand, as the pitch will carry, but in no case shall the volume of the sand exceed the volume of the pitch. The sand shall be fine and clean, and all of it shall pass a 20-mesh sieve. It shall be heated to a temperature of not less than 149° C (300° F) nor more than 205° C (400° F) and shall be between these limits when mixed with the paving pitch. The paving pitch shall be heated in kettles properly equipped with an approved thermometer, which shall register the temperature of the pitch. The mixture shall be flushed on the surface of the blocks and pushed into the joints with suitable tools, reflushing or repouring if necessary, until the joints remain permanently filled flush with the surface of the pavement. As little as possible of the mixture shall be left on the surface.

"The tar pitch shall comply with the following requirements:

1. It shall have a specific gravity between 1.23 and 1.33 at 15.5° C (60° F).
2. It shall have a melting point between 46° and 57° C (115° and 135° F), determined by the cube method in water.
3. It shall contain not less than 20% nor more than 35% of free carbon insoluble in hot benzol or chloroform.
4. It shall contain not more than 0.5% of inorganic matter.
5. It shall be free from water.
6. It shall have a ductility of not less than 60 cm at 25° C (77° F).

"The tar pitch shall be used on the work at a temperature of not less than 121° C (250° F) and shall at no time be heated above 163° C (325° F). It shall be delivered where directed by the engineer in time to allow for examination and analysis. In applying the filler, care shall be taken that the pavers are closely followed by the filler gang, and in no case shall the paving be left over night, or when work is stopped, without the filling of the joints being completed. In case rain stops the filler gang before its work is finished, the joints shall be protected by the use of tarpaulins, or other means, to keep out water. Under no circumstances shall the filler be poured into wet joints.

"B. Asphalt Filler. The joint filler used shall be the asphalt cement hereafter described, thoroly mixed with as much hot, dry sand as the cement will carry, but in no case shall the volume of the sand exceed the volume of the cement. The sand shall be fine and clean, and all of it shall pass a 20-mesh sieve. It shall be heated to a temperature of not less than 149° C (300° F) nor more than 205° C (400° F) and shall be between these limits when mixed with the cement. The asphalt cement shall be heated in kettles properly equipped with an approved thermometer, which shall register the temperature of the cement. The mixture shall be flushed on the surface of the blocks and pushed into the joints with suitable tools, reflushing or repouring if necessary, so that the joints remain permanently filled flush with the surface of the pavement. As little as possible of the mixture shall be left on the surface.

"The asphalt paving cement shall be obtained by the distillation of an asphaltic petroleum at a temperature not exceeding 372° C (700° F), and shall comply with the following requirements:

1. It shall be homogeneous.

2. Its melting point shall not be less than 54° C (180° F) nor more than 63° C (145° F).
3. Its solubility in carbon tetrachloride shall not be less than 98.5%.
4. Its penetration at 25° C (77° F) shall not be less than 60 nor more than 100, the penetration test being made with a No. 2 needle for 5 sec under a load of 100 g and the penetration at 38° C (100° F) shall not exceed three times its penetration at 25° C (77° F), the condition of time and load being as above established. The Contractor, before beginning work, shall obtain from the Engineer a statement in writing as to the penetration desired for any particular contract and a variation of not greater than ten points either way from this penetration will be permitted.
5. Its ductility at 25° C (77° F) shall not be less than 40 cm, the rate of elongation being 5 cm per min.
6. It shall not lose more than 3% by volatilization when maintained at a temperature of 163° C (325° F) for 5 hr, nor shall the penetration of the residue, after such heating, be less than one-half the original penetration.

"The asphalt filler shall be used on the work at a temperature of not less than 135° C (275° F) and shall at no time be heated above 177° C (350° F). It shall be delivered where directed by the engineer in time to allow for examination and analysis. In applying the filler, care shall be taken that the pavers are closely followed by the filler gang, and in no case shall the paving be left over night, or when work is stopped, without the filling of the joints being completed. In case rain stops the filler gang before its work is finished, the joints shall be protected by tarpaulins or other means, so as to keep out water. Under no circumstances shall the filler be poured into wet joints.

"C. Cement Grout Filler. After the pavement has been brought to a uniform surface, Portland cement grout shall be poured into the joints until it appears on the surface. The grout shall be broomed or scraped into the joints if necessary to fill the same, and the operation shall be repeated as the grout settles and before the initial set has taken place, until the joints are thoroly filled flush with the surface of the blocks. Immediately after this the entire pavement shall be broomed to a smooth surface. The blocks shall be wetted immediately before applying the grout.

"The cement grout shall be composed of one part of Portland cement and one part of clean, sharp sand. The cement and sand shall be thoroly mixed dry and only enough clean fresh water shall be added to make a grout which will flow to the bottom of the joints.

"The grout shall be machine mixed in a batch mixer approved by the engineer and shall be applied to the joints before the ingredients have separated. Particular attention is called to the importance of ascertaining the proportional amount of water to be used with the mixture of different kinds of cement and sand to give the best results, and when the most advantageous proportions have been ascertained, these shall be used.

"After the grouting is completed, and a sufficient time for hardening has elapsed so that a coating of sand will not absorb moisture from the cement mixture, ½ in of sand shall be spread over the whole surface and shall be kept damp until the street is opened for traffic. After the grouting is completed the street shall be kept closed and no carting or traffic allowed on any part of the grouted pavement until at least 7 days have elapsed. Should the bond between the blocks become broken, before the work is accepted, such defective work shall be regrouted or relaid and again barricaded, as previously described."

10. Construction Cost Data

The cost of construction work of any character will vary according to localities. Prices of labor and material are always different in different places, but if the correct quantities of labor and material are given for any construction, it is a simple matter for any engineer to apply the costs of these two items to his location; so that in presenting the cost of stone block or other pavements, it is intended to be accurate as regards the quantity of work done and the amount of material consumed for any locality, and to be accurate as to prices of labor and material where the cost of the work is given.

Borough of Brooklyn, New York City. The following is the organization actually employed in constructing granite block pavement in 1914.

Cement-Concrete Foundation

Labor		Materials per Cu Yd of Concrete			
Gang	Per Day	Item	Quantity	Price per Unit	Cost
1 foreman	$5.00	Cement..	1 bbl	$1.30	$1.300
2 men wheeling sand	4.00	Sand.....	0.44 cu yd	0.90	0.396
1 cement man	2.00	Broken			
4 blend mixers	8.00	stone...	0.88 cu yd	1.85	1.628
2 blend shovelers	4.00				
5 stone shovelers	10.00	Cost per cubic yard			$3.324
1 stone trimmer	2.00				
2 plank men	4.00	Material cost per cu yd			$3.324
4 concrete wheelers	8.00	Labor cost per cu yd			0.670
4 concrete rakers	8.00				
2 concrete rammers	4.00	Total cost per cu yd			$3.994
1 concrete broomer	2.00				
1 man at tail of mixer	2.00	Total cost per sq yd for 6 in			
3 fine graders	6.00	foundation			$0.666
1 engineer	4.75				
Use of mixer and team to haul	10.00				
	$83.75	Total 750 sq yd (125 cu yd) @ 11.2 cents.			
Total cost per cu yd based on laying 125 cu yd per day					$0.67

Granite Block Paving

Labor		Materials per Square Yard Granite Paved			
Gang	Per Day	Item	Quantity	Price per Unit	Cost
1 foreman	$5.00	Granite....	28 per sq yd	$2.00 sq yd	$2.00
7 pavers at $5.00	35.00	Pitch.....	20 lbs	15.00 ton	0.15
3 rammers at $4.00	12.00	Gravel....	0.04 cu yd	2.00 cu yd	0.08
7 pourers at $2.00	14.00	Sand......	0.03 cu yd	1.00 cu yd	0.03
8 laborers at $2.00	16.00				$2.26
	$82.00	Cost of materials per sq yd			$2.26
Total cost per sq yd based on laying 455 sq yd per day		Cost of labor per sq yd			$0.18
	$0.18	Total cost per sq yd			$2.44

Hence, as the concrete costs $0.666 per sq yd and the granite $2.440 per sq yd, the total cost per sq yd with 5% of the sum of the above items added for incidentals, $0.155, will be $3.261. The average price paid to contractors in 1914 was $3.53 per sq yd.

Minneapolis, Minn. The following is the organization used, the work being done by the city:

Grouted Stone Block Paving

1 superintendent, part time	$1.00
1 timekeeper, part time	0.50
1 foreman, per day	4.50
6 pavers at $3.50 per day	21.00
1 rammer, per day	3.00
1 sweeper, per day	2.50
6 tenders at $2.50 per day	15.00
1 water boy, per day	1.50
4 men grouting at $2.50 per day	10.00
	$59.00

This gang will lay 330 sq yd per day at $0.179 per sq yd. Stone costs $1.75 per sq yd. making a total of $1.929 per sq yd, not including foundation.

BALTIMORE. In 1914 (13 b), a recut block pavement cost per square yard as follows:

Breaking up old pavement	$0.09
Recutting old blocks	1.00
Hauling, laying and grouting	0.71
Total	$1.80

The average cost of new blocks laid was $2.80; thus there was saved $1 per sq yd.

Schenectady, N. Y. The following figures give the cost in detail for laying a recut granite block pavement in 1913, containing 2587 sq yd.

	Total		Per Sq Yd	
Labor, ripping up asphalt and concrete	$115.28		$0.0445	
Team hire, hauling asphalt and concrete	40.27		0.0156	
Labor, ripping up old granite blocks	78.76		0.0305	
Labor, regulating and grading subgrade	107.81		0.0417	
Team hire, hauling materials from subgrade	62.41		0.0241	
		$404.53		$0.1564
1 : 3 : 6 Cement-Concrete Foundation 4 in Thick	Total		Per Sq Yd	
Labor, mixing and laying concrete foundation	$308.27		$0.1192	
Material, cement delivered on job	263.35		0.1018	
Material, sand delivered on job	71.08		0.0275	
Material, stone delivered on job	216.22		0.0835	
		$858.92		$0.3320
1 : 3 Cement Mortar Bed, Thin	Total		Per Sq Yd	
Labor, mixing and placing mortar bed	$190.80		$0.0738	
Material, cement on job	224.42		0.0868	
Material, sand on job	62.80		0.0242	
		$478.02		$0.1848
Breaking, Dressing and Laying Blocks	Total		Per Sq Yd	
Labor, breaking and dressing granite	$1910.57		$0.7385	
Labor, sharpening and making tools	129.38		0.0501	
Material, sharpening and making tools	15.00		0.0058	
Team hire, shifting blocks	15.30		0.0059	
Labor, handling blocks to pavers	102.38		0.0396	
Labor, laying blocks	464.77		0.1796	
Labor, ramming blocks	16.98		0.0065	
		$2654.38		$1.0260
1 : 2 Cement Grout Joints and Surface	Total		Per Sq Yd	
Labor, mixing and placing grout	$120.66		$0.0466	
Material, cement on job	182.85		0.0707	
Material, sand on job	27.55		0.0106	
		$331.06		$0.1279
Overhead Charges	Total		Per Sq Yd	
Labor, foreman, assistant foreman, etc	$211.94		$0.0819	
Labor, watchman	142.87		0.0552	
		$354.81		$0.1371
Extra Work				
Repairs to side walks, etc		$111.18		$0.0430
Grand total		$5192.90		$2.0072

Unit prices: foremen, per day, $4; assistant foremen, per day, $3.50; block cutters, per day, $5; pavers, per day, $5; laborers and watchmen, per day, $2.25; teams, wagon and driver, per day, $5; horse, wagon and driver, per day, $4; Portland cement bbl f.o.b. cars, $1.24; sand, ton, f.o.b. cars, $0.25; crushed stone, 1½ in, ton, f.o.b. job, $1.75; crushed stone ¾ in, ton, f.o.b. sidetrack, $1.20.

The old blocks were 8 in deep and ranged from 12 to 16 in in length. The 16-in blocks were broken into four parts, making four blocks 4 by 4 by 8 in. The 12-in blocks were cut into four parts by splitting the blocks lengthwise, making two blocks 12 in long and 4 in deep, and these were broken in the middle, each making two blocks 4 in deep and 6 in long; so that a 4 by 12 in block would make four new blocks each 4 by 6 in, and a 4 by 16 in block would make four blocks 4 by 4 in on top and 8 in deep. In other words, each 12-in block would have a surface of 48 sq in, while the four new ones would have a surface of 96 sq in; each 16-in block would have a surface of 64 sq in; while the four new 4 by 8 in blocks would have a surface of 128 sq in.

The following figures are for another job in Schenectady containing 4189 sq yd covering, removing and disposing of old asphalt blocks, repairing foundation, recutting old 4 by 8 by 12 in blocks to 4 by 4 by 6 in blocks, laying in 1 : 4 mortar bed, and applying 1 : 2 cement grout and surface plaster.

	Cost Per Sq Yd
Grading and removing old materials	$0.1212
Patching up old concrete base	0.0443
Mortar bed	0.2033
Breaking, dressing and laying blocks	1.0339
Grouting joints and surface	0.1483
Overhead charges	0.1550
Extra work	0.0062
Total	$1.7122

Newark, N. J. The following are the figures given by Howell, (15) as the cost per sq yd for a pavement laid with recut blocks:

Blocks, 21 per sq yd at $0.03	$0.63
Paid clippers for work	0.53
Laying and handling	0.20
Sand	0.05
Concrete	0.65
Grading	0.10
Hauling	0.10
Grouting	0.12
Total per sq yd	$2.38

11. Durax and Kleinpflaster

Description. Small stone block pavements known as Durax and Kleinpflaster have been laid to a considerable extent in Europe, the former name being used in England and the latter in Germany. The principal feature of the pavements is the small irregular size of the blocks, approximating cubes 2½ to 4 in in size. At the present time practically all blocks are made with specially designed machines. An efficient operator at one machine can make on an average 2400 blocks in a 10-hr day. They are sufficiently irregular both in size and shape to permit them to be laid in arcs of circles of comparatively small radii and so that the joints will not be excessively large. By laying the courses in circular arcs practically none of the joints are parallel to any line of traffic. In Europe these blocks have been used to a great extent in resurfacing the broken stone roads where the traffic is too heavy for the macadam and to some extent on city streets. They have been used to a slight extent in pavements in some southern cities in the United States.

Table IV.—Character and Cost of Stone Block Pavements in 1915 in Several Cities

From *Engineering and Contracting*, April 5, 1916

*Price covers pavement, foundation, and shaping subgrade.
†Does not include shaping subgrade.
‡Includes taking up old pavement.

Construction and Cost Data. Germany (9). The Kleinpflaster stone block pavement on the Döberitzer Heerstrasse between Berlin and Charlottenburg is composed of a series of three stone course arcs averaging about 12 in in overall width between which Kleinpflaster cubes are laid diagonally. The cords of the rings average 7 ft and the middle ordinates 16 in. The size of the Kleinpflaster cubes vary in surface dimensions from 2½ by 2½ in to 3½ by 4 in. The widths of the joints vary from ¼ to ⅓ in. It is reported that this pavement was laid upon a gravel foundation with gravel filled joints. The width of the center drive of this famous boulevard, paved as above described, is 37 ft.

England. Victoria Road, Eltham (9). The current practice of constructing a Durax stone block pavement is typified by the method used in laying the Durax pavement on Victoria Road in Eltham in 1913. On a prepared macadam foundation, tarred sand was laid to such a depth that, after the Durax cubes were rammed, the depth of sand was between ¼ and ½ in. The alignment of the blocks and the number of arcs in a transverse section were controlled by iron pegs driven into the macadam foundation prior to the laying of the blocks. Strings stretched between these iron pegs served as guides for the placing of the stones from which adjacent arcs sprung. The largest cubes were laid at the center of the arcs and adjacent thereto, while the smallest cubes were laid near the springing lines. The arcs were so laid that the cords averaged 3 ft 6 in and the middle ordinate varied between 9 and 10 in. After the joints of the blocks were filled with clean stone chips, the blocks were well rammed. The final operation consisted in pouring the joints with hot pitch and covering the surface with gravel. The cost of this Durax pavement was 8 shillings ($1.95) per yd

super with foundation, the work being carried out by contractors under a 5-year maintenance contract. The blocks used in the pavement were furnished by the Durax Dustless Roads, Limited. This company manufactures these blocks in three grades, having the following limiting edge dimensions: 7 to 9 cm (2¾ to 3½ in), 8 to 10 cm (3¼ to 4 in); and 10 to 12 cm (4 to 4¾ in). One grade is furnished for the construction of a given pavement.

London Folkestone Road, Sidcup, Kent County (21). The granite cubes used were obtained 50% from the Durax Dustless Roads Company's Swedish quarries at Rixe, the remainder from the Company's Enderby quarry near Leicester. The size of the cubes was 7 to 9 cm (2¾ to 3½ in), giving a finished depth of paving of about 3¼ in. The grouting mixture was composed of coal tar pitch, tempered with creosote oil or tar, into which was stirred about 30% of fine, dried sand. The existing macadam was scarified and removed and the foundation thoroly consolidated by wetting and rolling. On this prepared foundation a layer of tarred limestone or slag chippings was spread to a thickness of ¾ in, and the cubes laid on this in intersecting segmental courses, the paving being afterwards thoroly consolidated by hand ramming. The grouting mixture was poured on the surface in a boiling state and forced into the interstices with a rubber squeegee, the whole surface being then covered with hot chippings applied before the grouting had solidified. This was consolidated by hand ramming and steam rolling. The report to the Board also states that there had been no repairs on this section from the date of completion, July, 1911, up to Nov., 1912. The original cost is given as 7 shillings 6 pence ($1.80). The traffic census between Aug. 15 and 21, 1912 showed an average daily traffic, 6.00 A. M. to 6.00 A. M., of 750 cycles, 638 motor vehicles and trailers, and 386 horse-drawn vehicles, giving an average weight in tons per yard width of carriageway of 506, the total width of carriageway being 21 ft.

Specifications. The following abstracts from specifications are typical of the practice of constructing Durax pavements in the United States:

The Durax cubes, which shall be of medium grained granite, showing an even distribution of constituent materials, shall be of uniform quality and texture, without seams, scales or discoloration showing disintegration, free from an excess of mica or feldspar, and equal in every respect to the sample in the office of the Engineer. The granite shall be such as will give about 30 000 lb per sq in crushing strength, combined with a uniform structure and toughness of 12 as determined by the method employed by the Dept. of Agr. of the U. S. O. P. R. from samples taken directly from quarry. Durax cubes shall have six irregular, approximately square surfaces, the edges of which shall measure not more than 4 and not less than 2¾ in provided the blocks used on any one city block shall not vary more than ¾ in in size, that is, either from 2¾ to 3½ in, or from 3¼ to 4 in.

On the concrete base shall be laid 1½ in of a cushion composed of clean sand and Portland cement in the ratio of 2 to 1. This cushion shall be made true with the use of a templet and shall be compacted by rolling to the satisfaction of the Engineer. On this cushion the cubes shall be laid carefully and close together taking pains to break joints as much as possible; the said cubes shall be laid in the form of an arc, the break in the arc to be 5 ft in width or such other width as directed by the Engineer. After the cubes are laid, they shall be thoroly rolled and made true to the crown of the street with a roller weighing not less than 5 tons, after which the surface of the Durax cubes shall be thoroly sprinkled several times sufficient to moisten the cushion after which the same shall be thoroly grouted with grout composed of clean sand and Portland cement in the ratio of 1 to 1. The surface of the pavement shall then be covered with sand and kept moist for a period of 1 week. Provided the Engineer so directs instead of filling the joints with grout, the same shall be filled with hot asphalt and hot sand mixed together in such proportions as may be required by the Engineer. If an asphalt filler is used the joints shall be dry before pouring and the asphalt used in the filler shall be an asphalt which will not become brittle at −18° C (0° F) nor flow at 49° C (120° F) and shall be waterproof, free from water or decomposition matter; shall adhere to the paving stones and shall remain ductile and pliable at all climatic temperatures to which it may be subject in actual use. The asphalt shall be mixed by volume with 50% hot sheet-asphalt sand. After an asphalt filler has been applied, the entire surface shall be covered with a coarse sand which shall be swept over the surface and joints.

12. Stone Trackways

Trackways have been built, both in this country and abroad, of stone slabs, brick, concrete blocks, steel shapes, and other materials. Stone trackways were used on one of the old toll roads in New York State as early as 1831. The slabs, which measured 24 in in width by 4 in in thickness, were laid with a gauge which would accommodate the vehicles. The space between them was paved with cobblestone. Trackways of rectangular stone blocks, averaging 12 in wide, 6 in thick, and of varying lengths, have been used in some cities of England and Scotland on steep hills or where the traffic is exceptionally heavy. These trackways, locally called " wheelers," are laid in many parts of Great Britain, but mostly in Liverpool and Glasgow. They are laid on streets with heavy grades, so as to reduce the traction. In Glasgow, in 1913, there were 10.75 miles of these " wheelers." The stones of which they are made vary in size from 10 to 15 in in width and from 6 to 8 in in depth, according to conditions. They cost about $1.40 per running ft. These " wheelers " too are often seen in the rural sections of England, where they are laid on steep grades, both in order to reduce the wear and tear of heavy loads and also to reduce traction, as in the cities. Granite trackways, made of slabs 2 ft wide, 1 ft thick, spaced 4 ft apart on centers, are used in several cities in Switzerland.

13. Crosswalks

In America it used to be customary to lay crosswalks at each street intersection in all stone block pavements to accommodate pedestrians. This was more necessary with the old style pavement than with the modern blocks, and the practice may be discontinued if the improved form of blocks is generally adopted. The character of the stone in the crosswalks should be the same as that in the pavement, so that the wear may be uniform upon both.

The Bureau of Highways, Brooklyn, N. Y., specifications for crosswalks, say: "They shall be 18 in wide, of a uniform thickness, not less than 6 nor more than 8 in in depth, and from 3½ to 8 ft in length, except that in special cases between railroad tracks they may be of such dimensions as may be approved by the Chief Engineer of the Bureau of Highways.

"The top shall be dressed to a surface not varying in evenness more than ¼ in. The sides and ends shall be dressed square down and the latter cut to a transverse bevel of 6 in in width, or to such other bevel as may be directed, and the jointing from top to bottom shall give joints not greater than ¼ in.

"The bridge-stones shall be laid in parallel courses separated by granite blocks, and shall be well and firmly bedded on a layer of sand spread on the foundation as prepared for the pavement. The transverse joints shall be broken by a lap of at least 1 ft, and be so laid as not to be parallel to vehicular traffic.

European Practice. In Europe in some cities crosswalks are provided, and in others specially dressed blocks are laid where the crosswalks would naturally be placed.

The London specifications in this respect say: "The crossings shall be formed of 4 by 7 in specially dressed Aberdeen granite setts, and two rows of 12 by 6 in flat kerbs laid on a bed of Portland cement-concrete at least 6 in thick, the surface of both concrete and granite being cambered transversely as directed by the Engineer. The flat kerbs and setts shall be laid in straight, close jointed, and properly bonded courses, all the joints being solidly grouted with Portland cement and Thames sand, as before described, well rammed, back rammed, finished to a true surface, and covered with a top dressing of fine shingle."

The Liverpool specifications say: "The crossings shall consist of three rows of 16 by 8-in granite crossing stones, and the remaining space shall be paved on each

side of the crossing stones, to the full width of the footway, in a similar manner to the carriageway. The crossing stones shall be of granite of a quality to be approved by the City Engineer, dressed perfectly true, and out of winding on the face; the sides and joints to be perfectly square and accurately dressed thruout their entire depth; the stones to be bedded in cement-concrete, the joints to be filled with shingle and grouted in a similar manner to the paving. A triangular groove 1 in wide by ¾ in deep to be formed along the upper surface of each stone. No stone to be less than 3 ft in length."

Glasgow requires for its street crossings all blocks dressed as follows: "Each crossing sett shall be axed on the top, jointed on the sides and ends, dressed on the bed, shall be level on the top and bed, and have sides and ends parallel and square; the axing, jointing, and dressing shall be equal to the sample to be seen in the Office of Public Works. Setts of each class shall be truly gauged. No variation in width or depth greater than ¼ in over or under the sizes specified on orders will be allowed. All setts must be free from cracks and flaws. Setts with bulges or hollows will not be accepted."

It would seem that possibly as good results could be obtained by having stones in the line of the crossings specially dressed as by the use of large, flat stones. The average price for crosswalks in Brooklyn, N. Y., is $0.75 per sq ft or $6.75 per sq yd, while the price for the blocks, Grade 1, was in 1914, $2.84 per sq yd. This would allow a difference of $3.91 per sq yd, which would considerably more than pay for the extra dressing of the blocks that would be required to make a smooth surface.

MAINTENANCE

14. Maintenance Methods

The cost of a pavement in any city, especially the cities of America, is difficult to obtain. It is questionable, too, of how much value this information would be, as in most instances American cities do not have money enough to keep their pavements in good repair, and too often the information would be the amount of money paid out for repair work rather than the actual cost of necessary repairs. Then, too, the character of the street upon which the pavement is laid makes a great difference. For instance, it would be a simple matter in any city to lay on a selected street a granite pavement which would last 50 years and would require practically no work for repairs during the entire time, while, on the other hand, a pavement could be laid on a heavy traffic street where it would only last from 10 to 15 years, and then only after heavy and constant repair.

European cities, as a rule, have stone block pavements of some form, except where streets have been repaved in recent years, even on residence streets. In 1913 a stone pavement on the principal street of Berne, Switzerland, which had been laid 25 or 30 years at least, appeared, considering the traffic and other surrounding conditions, to have an additional life of 25 years. The street was solidly built up, and there was little prospect of any change in conditions, so that the pavement would probably be undisturbed for years.

It is a fact, however, that it is the wisest of economies for any city to keep all its pavements, stone block as well as others, in the best of repair. The life of a stone pavement will depend entirely upon traffic, and the better its condition is, the less will be the effect of that traffic. Organized gangs should be kept constantly employed in going over the stone block pavements to keep them in good condition.

SECTION 20
BRICK PAVEMENTS

BY

WALTER WILSON CROSBY

CONSULTING ENGINEER, BALTIMORE, MARYLAND

GENERAL DATA

1. Historical Development

Brick Pavements, in the sense that they are highway surfacings laid with artificial blocks hardened by heat and made from shales or other mixtures of clay and sand, are of considerable antiquity. The Romans laid such pavements, where the brick or tiles were superficially 18 by 12 in. Holland, about 1700, was probably the first of modern nations to use brick similar to those now in use for pavements. Byrne (5) states that " the first brick pavement laid in the United States was in Charlestown, W. Va., 1872." Eldridge (29) gives credit to Monmouth Township, Warren County, Ill., for "being the first in this country to make experiments in the building of country roads with brick" in 1892. The brick used in Charlestown, W. Va. (10), in 1870 were side cut, repressed, hard burned building brick of high density and absorbing 4.5% on soaking 24 hr. Bloomington, Ill., and St. Louis also used brick between 1875 and 1882, but the pavements were unsatisfactory and no further effort was made to use brick until 1895. Wheeling, W. Va., put down an impure, fire clay paving brick in 1883 that was so successful as to make this one of the important pioneers of the paving brick industry from the confidence so inspired; some of these brick are still in use altho most of them were renewed after 2 years. Decatur, Ill., also put down a vitrified brick this same year (1883) that was made from a glacial clay, and this was still in use in 1909. The year 1885 witnessed the first substantial increase in the use of vitrified brick, as during that

year it was laid at Columbus, Zanesville and Steubenville, Ohio, and Peoria, Ill. By 1904, the importance of vitrified brick pavements had reached such a point that the organization of their manufacturers under the name of the "National Paving Brick Manufacturers Association" was had, and since that event, the progress in both the manufacture and use of vitrified brick for paving road and street surfaces has been rapid and considerable. For detailed historical data concerning brick pavements, see (30c).

Vitrified Brick. The earlier work was mostly of unvitrified brick similar to those used for ordinary building purposes, except that in most cases the effort was made to select the harder burned brick for pavements. In some cases, where they were readily available, more especially perhaps abroad, slag and scoria brick were used. Since the development of the vitrified brick, the use of unvitrified brick has been abandoned, and all modern brick pavements are laid with vitrified or slag brick. As a matter of fact, the term vitrified is misapplied, as the brick are not converted into glass by heat. Vitrification is approached but not reached in the manufacture, and annealing then takes place so as to produce a brick thoroly compact, hard, and tough, but not brittle. The term, however, has acquired such general use that it will probably continue as a means of differentiating brick so made, and perhaps really vitrified superficially, from those simply hard burned for ordinary building purposes.

The Development of the Use of Slag Brick Abroad has been more rapid than in the United States, largely due to the fact that the manufacture of such brick in this country is extremely limited, and the importation of the foreign block has, in most cases, been so expensive as to preclude their use in spite of their advantages in some particulars. In Canada, where their cost is approximately the same as that of the vitrified clay and shale brick, the use of the slag brick is relatively much larger. Their manufacture and use in the United States is now on the increase.

The Use of Brick Pavements seems to be on the increase, especially in the case of roads. Until very recently practically all of the brick pavements laid were on city streets, but their extension to many country roads has occurred since 1910. Their success for road surfacing has been considerable in most respects, except possibly as regards the economy factor. In some cases at least, they have not been successful from this point of view, in that their cost to date has been greater than need have been incurred under the local conditions or for satisfaction. Undoubtedly in some of these cases, however, the change of local conditions taking place to produce more severe conditions will, if the proper maintenance is accorded these pavements, ultimately show that the selection of the brick pavement in many of these instances was wise from the point of view of economy. See (56).

2. Characteristics

Cheapness. While an average cost per square yard of a vitrified brick pavement on a cement-concrete base may be approximately and conveniently taken at $2, it may often, because of local conditions, be less than this. The omission of the concrete base and the utilization of the local foundation material, which may be proper under certain local conditions such as suitable materials and light traffic, may reduce the cost per square yard to as low as $1.25. The greater availability of brick for the surfacing, when the availability and propriety of other surfacings are considered under the same conditions, may show the cost of the brick pavement to be a favorable figure beside the cost of the other surfacings being

considered. On the other hand, it frequently happens that the first cost of brick pavements will be considerably more than $2 per sq yd and that the first cost of other suitable pavements from readily available materials will be at the same time much less than this figure. In such instances, the selection of the brick pavement must be justified by circumstances which will offset their higher first cost. See (16).

The Maintenance Cost, being made up partly by the interest on the first cost, will be affected by economy in the latter. The future maintenance cost, that is, the actual cost of making repairs to the pavement, resulting from the amount of traffic the pavement gets and its ability to resist the strains of such traffic, will depend upon the propriety with which the selection of the pavement is made for the local conditions and the character and efficiency of the maintenance accorded the pavement. Assuming that the selection of a brick pavement in any instance is proper, and that the character and efficiency of the actual maintenance is good, it is claimed that the maintenance cost of brick pavements is low. It has been claimed that it is practically nil, but this claim is an exaggeration. Necessity for repairs invariably arises even tho the intervening periods may seem relatively long. When these repairs have to be made, the cost must be distributed over the period. The length of this period is affected by the character of the construction and the amount of traffic. With extremely uniform brick and proper workmanship, a much greater evenness of wear and absence of broken brick or depressions in the pavement relieves the necessity for repairs to a much greater extent than in cases where uniformity of brick is lacking and where proper joint filling and good workmanship generally are deficient. The difficulties of securing uniform brick and proper workmanship in the construction of the pavement are not inconsiderable, and are perhaps greater than in the cases of some other competing pavements.

Durability is the ease of making and infrequency of repairs. It is generally fairly high where brick pavements have been properly selected for local conditions. Ease of repair to brick pavements may be greater than in the cases of some other pavements because no special plant is usually required for the prompt correction of minor defects. For instance, the repairing of a plumber's cut in a brick pavement can be quite efficiently done without the use of machinery, whereas in the case of a bituminous concrete or sheet-asphalt pavement, it is questionable if the repairs could be successfully made in the absence of a heating and mixing plant. The strength and resistance to wear of brick pavements is limited, and they will not satisfactorily endure under the heaviest traffic, such as frequently prevails in large cities especially along the docks or freight yards, even when the pavements are laid in the best possible manner from the toughest selected brick.

Resistance to Traction of a brick pavement is relatively light. The following table will give an idea of the relative values of different pavements in this respect:

Character of Surfacing	Resistance in Pounds per Ton	Authority
Sheet-asphalt	17	Gordon
Brick	26	Eldridge
Granite block	35 to 132	MacNeil and Rumford
Gravel	75 to 320	Bevan
Macadam	30 to 160	Morin and Gordon

The figures for bituminous concrete and for cement-concrete surfacings are not available. Those for bituminous concrete would probably be somewhat higher than for sheet-asphalt and might be considerably higher, as would also be the case with the sheet-asphalt itself during periods when the bituminous cement became soft under heat. Brick pavements would not be so affected. The figures for cement-concrete would probably be higher than those for sheet-asphalt or brick, but probably less than those for bituminous concrete when conditions are most unfavorable for the latter.

Non-Slipperiness. As the slipperiness of a pavement depends not only upon its character but upon the condition of the surfacing, comparisons of slipperiness can only be made under the assumption that conditions of the surface, such as are affected by the cleanliness of the pavement for instance, are the same. These surface conditions are further modified by weather and climatic conditions. Cement grouted brick pavements are smoother than those with bituminous filled joints, and consequently to some extent offer less foothold for horses. This is especially true when the dirtiness of the two surfaces is the same, because the depressions in the bituminous filled joints do not permit the slipping of the horses' shoes to the extent that will occur on the smoother surface of the cement grouted pavement. The cement grouted brick pavements, however, are not generally as slippery, especially in cold weather, as bituminous surfaces, and the latter seem to become slippery more readily in the presence of adventitious products than do even the cement grouted brick pavements.

Sanitariness. Brick pavements, if kept clean, are highly sanitary, because of their imperviousness. In the case of hillside brick or of pavements with bituminous joints, where depressions along the joint lines exist to a greater or less extent, decomposing matter may be held for considerable periods and such pavements are not as sanitary as the cement grouted pavements where the surface is smoother. On the other hand, when the regular cleaning of the pavements is defective for any reason, there are no qualities inherent in the brick pavement, such as do exist to a certain extent in the bituminous pavements, which interfere somewhat with the development of bacteria. Many bituminous materials have a considerable effect toward preventing or interrupting the growth of bacteria in the organic matter reaching their surfaces, and in this way tend to increase the sanitariness of their immediate surroundings. With both cement grouted brick pavements and bituminous pavements where the surface is quite smooth, the dustiness, which is a consideration under the head of sanitariness, may not be seriously objectionable even tho maintenance conditions are not ideal. In these cases the traffic itself may keep extraneous matter so swept to the sides of the roadway as to prevent its becoming objectionable by its presence. With the rougher surface brick pavements, such as those with bituminous joints or of hillside block, the conditions as to dustiness in the event of inefficient maintenance and cleaning are more likely to be objectionable. Waring (9), in 1896, said that if all the streets of New York City were given, where the grades would permit, a smooth pavement and a proper relation established between the pavement and the street car tracks, the cost of sweeping the entire city would be reduced by $500 000 per annum. Waring used the sheet-asphalt pavement as an example of a smooth pavement, but the application is equally as great in the case of properly constructed and maintained cement grouted brick pavements, which are as easily cleaned in most cases as the sheet-asphalt. Brick pavements with bituminous joints are not as easily cleaned as bitum-

inous pavements, but they are more easily cleaned than cement-concrete pavements, because of the greater porosity of the latter and as the usual rough surface of the cement-concrete pavement gives greater adhesion to foreign matter coming on it.

Noiselessness. The importance of this factor in a pavement is being more and more appreciated. One serious objection that has been raised to brick pavements in the past, and is still interfering with their selection in many cases, is that they seem to be comparatively noisy, coming perhaps second only to stone block in this respect. As a matter of fact, there have been cases where it was claimed that they were even more noisy than the stone block they replaced. In a letter addressed to the Chairman of the Paving Commission of Baltimore City in 1914, certain abuttors on a street containing one street-car track, and formerly paved with granite block on a gravel foundation, stated that "the brick are noisier than the Belgian blocks they replaced." The new construction consisted of sheet-asphalt from each curb to the nearest rail and vitrified brick with cement filler between the rails, all being laid on a cement-concrete base. Similar instances of an apparent increase in the noisiness by the substitution, within the street railway areas on a number of streets in Baltimore, of brick for stone block or other pavements, compels the consideration of this matter. Unquestionably the brick are more resonant than the more massive stone block, bituminous concrete, or even cement-concrete and macadam. Furthermore, the smoother surface of the cement grouted brick pavement may act as a better reflector to the sound produced upon it than the rougher surface of the other pavements, such as stone block for instance, where the surfaces of individual blocks are probably not as smooth as the brick and the surface of the pavement itself does not approach as closely to a single plane as does the surface of the cement grouted brick pavement. Consequently the sound may be more or less broken up in the case of the stone block surface and not so directly and effectively reflected. The reflection of sound may be compared perhaps to the reflection of light which is normally most efficient from a polished and non-absorbent surface like that of a mirror of silvered glass. The comparative noiselessness or noisiness of cement grouted and bituminous filled brick pavements is a controversial question, and until some standards for measuring noise have been devised, a settlement of the question in any case will probably be largely on a basis of opinion. With a cement filler the reverberating qualities of the brick pavement are at the maximum and any hollow rumblings, such as frequently occur from unequal bedding of the brick and the displacement of the sand cushion are more readily transmitted to adjacent stores and buildings, and apparently magnified there. The brick pavements with bituminous joints do not produce the roaring hollow sound which so often emanates from cement grouted brick pavements and which is frequently objected to seriously. On the other hand, the pavements with bituminous joints do give forth a sharp rattling noise owing to the inevitable wearing out or sinking of the bituminous filler between the brick and the striking of the hard tires of vehicles on the edges of the brick, and this noise is sometimes seriously objected to. The noiselessness of bituminous pavements and of macadam is extreme, especially in the case of the former. The noiselessness of cement-concrete is usually nearer that of macadam than is the case of any brick pavement.

Acceptability or agreeableness to æsthetic or personal demands on the pavement will be determined by local conditions and the character of the

pavement. Under some conditions, the light color of fire clay brick is an argument for its selection. In others, it may be an argument against it, and the same may be said of the reddish colored shale brick and the bluish or grayish slag brick. If the first cost of the pavement is largely paid by the abutting property owners, it may be fair to take into consideration, when the selection of the surfacing is to be made, the preferences of these abuttors for any peculiarities of a particular kind of pavement.

Favorableness to Travel, meaning the ease and comfort enjoyed in driving over a pavement, may or may not argue for the selection of a brick pavement according to the character of the traffic. If the traffic consists largely of horse-drawn pleasure vehicles, the rigidity of a brick pavement will quite likely be offensive, and such a pavement as a bituminous pavement with its greater resiliency may be preferred. Brick pavements seem a little more rigid than some cement-concrete pavements, altho there may not be much difference in this respect. Further statements as to the relative advantages and disadvantages of brick pavements may be found in Sects. 4 and 24.

3. Foundations and Curbs

Brick pavements are laid both with and without artificial foundations. Modern practice generally calls for an artificial foundation of Portland cement-concrete to be provided. There can be no question, in view of the extremely satisfactory experiences in many places where an artificial foundation has been omitted, that a practice of always providing a concrete foundation would be extravagant. A subgrade of gravel or sand properly prepared is frequently all that is necessary to give an ample foundation for a brick pavement, especially where the traffic over the latter is not likely to be of the most severe type within a reasonable period. An excellent instance of the satisfactory wear of a brick pavement on a sandy base and under fairly heavy traffic may be found on West Chase St., Baltimore. This pavement was laid in 1902, and was in excellent condition in 1916. The street is on the crest of a slight ridge running east and west, the subgrade is gravel or sandy gravel and the drainage naturally is all that could be desired. Other instances of the successful omission of concrete foundation may be found in the naturally sandy sections of such towns as Miami, Fla., and elsewhere. It is absolutely necessary, where an artificial foundation is to be omitted, that the natural foundation or subgrade shall be properly prepared by thoroly and evenly compacting the same and by carefully shaping it so that a uniform support and cushion may be accorded the brick pavement. The cost should be but little greater than the cost of the same work necessary before the placing of the concrete or other artificial foundation. The saving in first cost of the pavement will be from 50 to 75 cents per sq yd, and in the annual cost of the pavement, interest on this saving may be upward of 3 cents per sq yd.

The Natural Foundation or subgrade for a brick pavement should be carefully prepared whether or not an artificial foundation is to be placed on it. The importance of proper preparation of the natural foundation, in cases where the cushion and wearing course are to rest directly on the foundation, is often greater than when artificial foundations are to be provided, particularly in view of the greater difficulties sometimes encountered with the work of preparation in the former cases.

In any event, the somewhat usual practice of neglecting the preparation of the natural foundation and of relying on the artificial foundation to

make up for the defects of the natural foundation should be avoided. The natural foundation must be properly drained and thoroly compacted and, as nearly as may be practicable, brought to the proper grades, cross-sections and uniformity of surface, if economy in the design and construction of the subsequent work is to be expected. In these respects, the importance of the proper preparation of the natural foundation for a brick pavement and of an artificial foundation differs along no line except in degree perhaps, from the importance of the proper preparation of the foundation and subgrade for a macadam road-crust. The natural foundation should preferably be thoroly consolidated by a roller similar to that used in macadam work and, when once prepared, should be kept as free from disturbance as possible during the interval occupied by placing the artificial foundation. Any natural foundation which may be expected to suffer displacement, or to permit a displacement of the sand cushion placed on it, should have its defects in these respects remedied, or it should be supplemented by an artificial foundation over it.

Laylin (42) states, that "Many of the brick pavements in northern Ohio on streets and roads having a sandy or gravelly soil, are laid on natural bed foundation, and where traffic is light or medium, such streets are giving first-class service. Many such streets have been in use twenty years and more, and they give every evidence of being good construction." See also (21) and (39).

Rolling. The natural foundation should always be thoroly compacted, where practicable by rolling as referred to in Art. 9, even when an artificial foundation is to be placed thereon. In cases, such as of extremely sandy road-beds, where steam rolling may be impossible, compaction by a horse-drawn roller may be the necessary resort. A steam roller should be used whenever possible and the embankments and subgrades thoroly rolled, any depressions being filled with material similar to the rest of the foundation and rerolled until the surface is uniformly firm, even and at the proper elevations.

Artificial Foundations for brick pavements are, as has been noted, generally of Portland cement-concrete. The usual practice has been to make concrete foundations 6 in in thickness, but it is likely that some extravagance has been incurred by the adoption of this convenient figure. This is especially true where the filling of the joints in the pavement has subsequently been of high character and with Portland cement grout. Brick pavements are not expected to be economical under the most severe type of traffic, and therefore, where other conditions justify the selection of such a pavement, it is also quite frequently true that a 4 or 5 in concrete foundation will answer every purpose, and permit a saving to be made, especially under the modern practice of more carefully and thoroly preparing the subgrade. Other kinds of artificial foundations for brick pavements have been used, such as broken stone, gravel or slag roads, heavy layers of compacted gravel or sand, brick laid on a layer of sand, and plank. The use of the brick and plank foundations has been found unsatisfactory and has practically ceased. See (33).

Uniformity and Evenness of Surface in the case of rigid artificial foundations are especially important, because of the relatively greater emphasis in the results brought about by the greater rigidity usually had from artificial foundations. Lack of uniformity therefore is more apparent on the surface of the pavement in course of time, than would be the case where there was lack of uniformity at the start as in the instance of natural

foundations. Evenness of surface for artificial foundations is necessary in order to secure uniformity in the thickness of the cushion. The importance of this uniformity is set forth in Art. 11. The tendency is increasing to require greater attention to the securing of a most even surface of such artificial foundations as cement-concrete.

Macadam Foundations have been used to support wearing courses of vitrified brick with more or less success. If the macadam has been thoroly compacted and settled into an enduring and reasonably rigid form, and the surface of the old macadam was not so uneven as to permit too great a variation in the thickness of the sand cushion, the results have been fairly satisfactory. On the other hand, where the macadam was insufficiently rigid or compact and so uneven on its surface as to require a sand cushion greatly varying in thickness at different points, the final results were unsatisfactory.

Broken Stone, Slag or Gravel Foundations have been more or less successful on the same principle. The defect of such foundations, usually rather loosely compacted, is that they permit the escape of a certain amount of sand cushion down into their interstices, which results in uneven settlement and often breaking up of the brick wearing course.

Rolling. The artificial foundation may or may not properly be rolled, according to its character. At any rate, it should be thoroly and uniformly compacted by such means as are most appropriate. If of broken stone, gravel or similar material, it should be thoroly rolled to the utmost possible compaction by a 10-ton three-wheeled steam roller. The use of a double drum roller will be unsatisfactory because of the uneven compaction resulting from such use of this roller. The bridging of compressible areas in the material by the long drums results in places being left in the layer which afterward produce unevenness in its surface and eventually in the surface of the pavement itself. With a three-wheeled roller, these weak spots should be discovered and may be remedied before being covered up. Cement-concrete is not usually rolled after being mixed and placed tho it may be. The effort is usually made, however, to compact the concrete to some extent at least by ramming it in place. While this does produce some degree of compaction, the uniformity of compaction is questionable in many cases and rolling, if practicable, would be better. Broken stone, rolled and then grouted with cement mortar so as to produce in situ a cement-concrete would form a strong foundation for a brick pavement but the difficulties in the way of securing a sufficiently even surface uniformly at the proper elevations so as to provide for a uniform thickness in the sand cushion may be insuperable.

Curbs have usually been considered necessary along brick pavements for the purpose of preventing the outside brick from breaking away under traffic crossing from the pavement to the shoulder and the consequent ultimate destruction of the pavement. Wooden curbs have been used with more or less success in many cases of country roads. Usually it has been considered better practice to build cement-concrete curbs from 4 to 6 in in width and extending as low as the base of the artificial foundation. The objection to such curbs is their first cost and the extreme difference in rigidity between them and the material forming the shoulder outside of them. This results in a tendency for a rut to form along the curb and just outside of it in the shoulder material which rut serves to collect water which will materially affect the foundation. Further, unless the shoulders are well maintained outside the curb, the wheels of vehicles attempting

to reach the pavement from the shoulder, find difficulty in climbing up over the edge of the curb, and if iron-tired, tend to destroy the curb itself. A suggestion for obviating the difficulties produced by curbs, and tried successfully to some extent, consists of constructing on a cement-concrete foundation a lug projecting upward from the upper surface of the concrete about 2 in just outside the edge of the sand cushion of the pavement. This necessitates making the concrete foundation from 3 to 6 in wider than the pavement in order to give a substantial width to each lug, and results in a sunken curb holding the sand cushion and the lower edge of the vitrified brick in place. The cement filler, together with the support of selected shoulder material against the outside of the brick, is claimed to furnish sufficient strength for keeping the brick in place, and at the same time to avoid in part at least the cost and other objectionable features of a rigid curb along the edges of the pavement.

MATERIALS

4. Shale and Fire-Clay Brick

The Three Principal Paving Bricks now in use are the vitrified shale brick, vitrified fire-clay brick, and the slag or scoria blocks. Probably the use of the shale brick is at present greater than that of the other two combined. The shale brick are made of a proper mixture of suitable clay and shale, dependent upon the characteristics of each of the materials available in a given locality. The mixture is carefully and intimately made after the materials have been ground or otherwise prepared so as to permit their proper incorporation, and every effort is, or should be, made to obtain a homogeneous mixture. The mixing is done with the aid of water, and when of the proper consistency, the material is passed thru rolls, cutters and presses to form the individual blocks. These blocks are dried and then roasted in kilns until an approach to vitrification of the blocks is had, when the fires are reduced and the contents of the kilns gradually cooled or annealed. Modifications in the above processes produce different types of bricks. See (36).

Repressed Brick are made by repressing in molds, before roasting, the rough brick as they originally come from the cutters. Most repressed brick have projections in the form of lugs or raised letters on one or both sides, intended to bring about a slight and uniform separation of the rows of brick when laid in a pavement, with the idea that better joints may be had thereby. Some repressed brick have letters on their sides depressed into one face in order to permit the joint material to get a better hold on the brick.

Wire Cut Brick are formed directly from a ribbon of the soft material proceeding from the mixing machine, and are not repressed. They are of both kinds, smooth and with lugs. They are generally somewhat rougher in appearance than the repressed brick, but it is represented that they are more uniform, and both stronger and tougher than repressed block, because the repressing is claimed to disturb the molecular structure injuriously.

Vertical Fiber Brick are so cut from the ribbon of material that the surface of the brick exposed to traffic, as ordinarily laid in a pavement, is perpendicular to the axis of the ribbon as it comes from the rolls. Any fibers in the ribbon would therefore be perpendicular to the surface of the brick when so laid, as is the case with the wood fibers in a wood block pavement. See (27).

Tucker (54a) presents the differences between repressed brick and vertical fiber brick as follows: "The first difference relates to putting the fiber of the brick in a vertical position in the pavement. Experiments with an auger machine prove conclusively that, as the clay column is forced thru the die of the auger machine, there is a well-pronounced arrangement of the plastic material in concentric layers. This arrangement of material is closely represented by the fiber in wood. The clay column is cut into blocks by wire in the usual fashion, but instead of being passed to the repressing machine, the green blocks are immediately passed to the dryers and thence into the kilns. The auger machine expends perhaps 75 h p of energy in compressing the material and building up the fibrous structure just mentioned. These blocks are ordinarily passed to the repressing machine where the movable sides of the die bring a heavy pressure to bear on the six surfaces of the block, effectually upsetting or breaking down the fibrous structure previously obtained besides expending a considerable amount of energy to undo what the auger machine has just done.

"Other differences are that the repressed brick has smoother surfaces, is habitually given rounded edges, and usually carries the maker's name. The new style of block is purposely left as square-edged as the process of manufacture will permit, is cut by a coarse wire with a view to producing a roughened surface, and therefore has only the four smooth surfaces given by the sides of the die in the auger machine. It has been common practice to so proportion the repressed brick that each brick went into the pavement lying on its side so far as the fiber was concerned, tho on edge as to size, the effect being as if wood paving blocks were laid with their grain parallel to the direction of traffic, instead of having it vertical. On the hypothesis of a fibrous structure it appears that the resistance to wear should be much greater if the fibers are placed vertically in the pavement instead of lying flat since the tendency to spall or break is thereby greatly lessened. The vertical-fiber method of laying brick is now carried out. The dimensions of the brick are 8¼ by 3½ by 3 in, and they are laid flatwise; that is, with the 3-in dimension vertical.

"From the manufacturer's standpoint, there is a considerable saving of material due to lessening the pavement thickness. Also, as the bricks have their larger dimensions flatwise, a less number of bricks is required to the square yard and substantial savings may be thereby made, while the consequent lessening of cost tends to popularize brick paving. Also the cost of power required to operate the repressing machine is saved, as well as the extra hauling required to put the brick thru it." See (54b).

Fire-Clay Brick are made from fusible, plastic clays, selected for the purpose, with or without an admixture of sand, in much the same manner and form as are shale brick, tho usually of smaller size than the latter. They are supposed to be somewhat softer and less brittle than shale brick, but the difficulties of securing proper materials and of their manufacture has interfered with their serious competition, except locally, with the shale brick, and their use is much less extensive.

5. Scoria or Slag Blocks

Scoria or Slag Blocks are usually cast in molds from the molten slag forming the waste or by-product from blast furnaces for producing iron. These slags vary a great deal in composition according to the character of the iron ores being used, and the character of the flux employed for their purification. The acid slags, being more vitreous, are the ones suitable for brick making. Not all of the acid slags, however, can be used to advantage for slag brick, and the details of the methods of manufacture are important. Proper annealing of the brick is somewhat difficult but absolutely necessary for success. Good slag brick appear to stand up better, under fairly heavy traffic, than do shale or fire clay brick. They are often, however, unfairly reputed to be somewhat more slippery than the others.

An Analysis of a Slag Block taken at random from a lot being used in 1914 in Balti-

more, Md., and supposed to have come from England, was as follows: Size of block, 3½ by 4 by 8 in, edges bevelled on one face; weight, 10.56 lb; specific gravity, 2.684.

Chemical Analysis

Silica	34.43%
Alumina	29.68%
Oxide of iron	4.00%
Lime	11.73%
Magnesia	10.02%
Alkalies	1.15%
Sulphuric acid	8.99%
	100.00%

6. Physical Properties of Brick

The quality of a paving brick depends upon its density, hardness, imperviousness, resistance to cross breaking and crushing strains, toughness, and uniformity or homogeneity of character.

Form and Size. Paving brick are, approximately at least, rectangular in section each way, tho the edges of the faces intended to be exposed in the pavement are frequently rounded slightly at the corners, especially in the case of repressed and slag brick. Originally, paving brick were made in various sizes, some makes being practically identical in size with the ordinary building brick, that is, 2 by 4 by 8 in, while variations from this size up to what might be called tiles, 12 by 12 by 4 or 6 in thick were not uncommon. The standard size for shale brick now is 3½ by 4 by 8½ in; for fire clay brick, 2½ by 4 by 8½ in; and for slag brick, 3½ by 4 by 8 in. In repressed brick, if the edges are rounded the radius should not exceed 3/16 in and any lugs or projections on the side of the brick should be not greater than ¼ in beyond the plane of the side. Variations in width and depth should not exceed ⅛ in, nor in length be more than ½ in.

Reduction in Depth of Brick (49c). "Since the advent of the monolithic and semi-monolithic construction there is a tendency among paving engineers to reduce the depth of the brick from 4 to 3 in. If a 3-in brick laid directly in the green concrete, or on a cement-sand superfoundation will give as durable a wearing surface as a 4-in brick, there would be considerable saving in the cost of brick paving, especially in districts at a distance from the brick plants. The paving engineer in preparing his estimates should investigate the saving in 1 in of brick as compared with 1 in of the prepared foundation, and prepare his plans and cross-section of pavement accordingly. In the manufacture of 3-in paving brick there is a little saving in cost at the plant; the main saving, however, being in the transportation charges. A thousand 3-in paving brick weigh about 7500 lb which is a saving in weight of approximately 2500 lb over that of a 4-in brick. This would mean on a shipment of brick to New York City from the eastern Ohio district a saving of about 16 cents per sq yd of brick surface. To the contractor there is a considerable saving in the use of a 3-in paving brick. He can haul one-third more brick per load; the manipulation of handling and laying would be faster; they would require one-fourth less grout or bonding material and also require less excavation. Many engineers are taking advantage of these savings and there has been an increasing demand for 3-in brick during the year 1916."

Number per Square Yard of Pavement. With fire-clay brick of the size above given, allowing for joints, 58 will be required to the square yard of pavement if the brick are laid on edge, and 38 brick per square yard if they are laid flatwise. With shale brick laid edgewise, 43 will be required to the square yard, and 38, if laid flatwise.

The Color of shale brick is usually a dark red, more or less mottled or speckled with small blue or yellowish white spots; that of fire-clay brick is usually yellow or yellowish white; and that of slag brick, light blue or bluish gray. All these paving brick have a skin or superficial coat more

vitreous in character than the interior of the brick, and generally darker in color. As this skin is broken or worn off, the wear of the exposed interior mass is often perceptibly different under traffic. Too great a variation in color between the outside and the inside of any brick therefore indicates a difference in character and possibly to an objectionable extent.

The color of paving brick is no criterion for comparing brick made from different clays, tho for a given clay it may be a reliable guide, if burned under the same conditions, as to the heat it has received. Uniformity of color thruout a broken brick is a valuable guide for checking up the work of the burner, as too dark a center shows varied firing, while a too light-colored center shows insufficient time in holding the heat. Homogeneity, density and degree of vitrification may be judged by the appearance of the fracture on breaking a brick, and there should be apparent no large spots of unfused matter in glassy or spongy spots, no lack of uniformity, no shakes or marked laminations.

Density is a desirable factor in paving brick, as, other things being equal, with the denser brick, the greater quantity of wearing material is had in a given space. The density is usually expressed in terms of specific gravity, the shale brick ranging from 2.05 to 2.55; the fire-clay brick from 1.95 to 2.30; and the slag brick from 2.5 to 3.0.

Hardness is the property resisting the attrition of the tires, especially when the brakes are applied, and of horses' shoes. It is probably next to toughness as an important requisite of good paving brick.

Imperviousness is an indication of the degree of vitrification, as a sound and perfectly vitrified brick is non-porous. Fire-clay brick rarely absorb less than 2% on 24 hr soaking in water, and often over 5% without much injury to their use in pavements. Shale brick range from 1 to 2½%, while slag brick show even less absorption. Too little absorption may be indicative of brittleness. The National Paving Brick Manufacturess Association takes the position that the absorption test is unnecessary, in that the rattler test gives all the necessary information.

Tillson (8) says: "The porosity of a paving brick is one that can be easily tested and has received considerable attention by engineers. It has been generally considered that 2% is the maximum amount of absorption that a good paving brick should be allowed. Very few good shale bricks will exceed this, but bricks manufactured from fire-clays, which from their nature are incapable of vitrification, will in almost every case absorb more than this amount. It has generally been considered that the danger of absorption in a paving brick was similar to that in building bricks, that is, its liability to disintegrate under the action of frost, but it must be remembered that paving brick and building brick are two different substances. In order to reach the point of vitrification, brick have been subjected to such severe heat that they have acquired a strength which is fully able to withstand all actions of the frost, and tests made have borne out this view of the question. Tests for porosity, however, are valuable, as they indicate, in a way not otherwise possible, the amount of vitrification that has taken place, especially on the exterior. If the brick are thoroly vitrified they cannot be porous and absorb any appreciable amount of water."

The Resistance to Crushing and Cross-Breaking Strains should be regarded in the light of the strains likely to come on any individual brick in the pavement. Usually these tests are omitted. Paving brick vary greatly in crushing resistance, ranging between 4 000 and 30 000 lb per sq in. Cross-breaking resistance ranges from 1 000 to 3 500 lb per sq in of cross-section when tested between supports 6 in apart and loaded midway. With the sand cushion under a brick pavement and the other precautions taken in constructing a pavement, a test for the cross-breaking strength is rarely needed.

Toughness is a most vital property in a brick for pavement purposes, for toughness is the ability to resist the most severe of the destructive agencies of the pavement, that is, the shocks of traffic. The rattler test (see Art. 9) for toughness has been fairly well standardized. As a matter of fact, this test for toughness, when properly carried out, frequently obviates the necessity for any of the other tests above mentioned, except perhaps those made thru visual inspection as already indicated. A test for toughness or resistance to spalling, or chipping off at the edges under shock, has been proposed, but it has not as yet been standardized, nor does it seem to have been generally accepted in principle. Green (34) has conducted a series of tests, with the Page impact machine, to investigate the relationship between toughness and the loss on abrasion in the standard rattler tests. Typical results of tests are given in Table I.

Table I

Method of Manufacture	Average Toughness of Surface Cores	Percentage Rattler Loss	Method of Manufacture	Average Toughness of Surface Cores	Percentage Rattler Loss
Wire Cut . . .	10.5	15.5	Repressed . . .	9.0	15.0
Wire Cut . . .	12.0	16.0	Repressed . . .	7.5	15.1
Wire Cut . . .	10.0	16.3	Repressed . . .	6.0	16.8
Wire Cut . . .	10.0	17.2	Repressed . . .	7.5	16.9
Wire Cut . . .	9.0	19.4	Repressed . . .	7.5	17.6

The Uniformity or Homogeneity of paving brick in all respects is most important, and this applies to a lot of brick as well as to the individual specimen. It is obvious that variation in the individual bricks composing a pavement will result in lack of uniformity in the resistance of the pavement to wear under traffic, just as lack of uniformity in the composition of the individual specimen will result in lowering its resistance to wear. Brick pavements can frequently be so unevenly worn as to be unsatisfactory in their condition, or even to warrant their relaying, because of the numerous holes in the surface caused from the more rapid wear of one or two brick which have been surrounded, as laid, by more resistant brick. Had the brick worn more uniformly thruout the pavement, while the total wear of the pavement would have perhaps been greater, its existing condition of surface would have been far less unsatisfactory. A great defect of the tests now generally made on paving brick is that they do not usually provide for special consideration on this point. See Arts. 8 and 9. See also (13). For about 1000 records of brick tests, see (44a) and (44b).

Tillson (8) says: "All products of the same kiln should be uniformly burned. While this is sometimes difficult to be obtained, if proper care is exercised in the burning, and the brick are selected at the kiln before shipment, satisfactory results can be secured in almost every instance. A better pavement will result from a lot of brick that are uniformly burned, even if not fully up to the required standard, than from a lot which is perhaps one-half perfect and the other half somewhat inferior, for when subjected to traffic the harder brick will maintain their size, while the softer brick will wear and the entire surface soon become rough and uneven and very disagreeable for travel."

Tests on Individual Brick. Provision should be made for securing information as to the uniformity, or lack of it, in the losses of the individual brick, or, as they are samples, of the lot of brick they represent. The

necessity for uniformity among the individual brick composing a pavement has already been generally recognized. Further discussion on the subject may be found in (24) and (47a). Specifications such as those of the Am. Soc. Test. Mat. (see Art. 9) or of the Am. Soc. Mun. Imp. should have added to them a clause like that in the specifications of the Md. Road Comm., thus: "The losses in the rattler test shall not average more than ......, nor shall the difference between the maximum and minimum losses in the rattler test exceed ten points." See (44b), (51a), (51b) and (52b).

Illinois Practice (51a). "The bricks are marked with a compressed air drill making a hole only 1/10 in in diameter, and ¼ in deep (see Fig. 1). Approximately 200 rattler tests have been performed during the past years, using the above scheme of identifica-

tion, and it has been noted that very few of the bricks which broke, or chipped, in the rattler were broken thru a drill hole. A number of comparative rattler tests were performed with marked and unmarked bricks, and it has been found that the drilling of the small holes used in marking did not cause any appreciable increase in the rattler loss. It has been noted in practice that a shipment of bricks showing a fairly high average rattler loss and uniform wearing qualities, will often make a better pavement than bricks showing a low average loss, but also rather wide variations in wearing qualities."

Newark, N. J., Method and Tests (40). "The system of marking bricks, which is in use in a number of cities, is as follows: (1) drill hole on the flat part; (2) one drill hole on the top part; (3) one drill hole on each flat portion; (4) one drill hole on top and bottom; (5) one drill hole on the end; (6) one drill hole on each end; (7) two drill holes on flat part; (8) two drill holes on the top part; (9) one on top and one on end; (10) blank. The drill holes can be put in the bricks by a man accustomed to do that kind of work in from 20 to 25 min. There are but 15 holes to be drilled."

7. Sampling Brick

The following method was adopted at the First Conference of State Highway Testing Engineers and Chemists held under the auspices of the U. S. O. P. R. in Feb., 1917.

"**Inspection.** Vitrified bricks may be inspected and tested at the point of manufacture, or they may be sampled at the point of delivery, and representative samples submitted to the laboratory for testing prior to acceptance of the shipment.

"**Plant Inspection.** Whenever practicable the inspection and testing of vitrified bricks shall be carried on at the manufacturer's plant. The choice between plant inspection and sampling at point of use should be based om the average number of brick to be shipped from the plant per day, and the total number required for the particular piece of work. Whenever conditions permit, samples should be taken directly from the kiln during the process of emptying. One or more sets of tests, depending upon the size of the kiln, each set consisting of three separate tests, should be made on each kiln. Each test in a set cf three should represent approximately a single degree of burning, based on the position of the bricks in the kiln, and all ten of the bricks in a single test should be of the same approximate degree of burning. The average abrasion loss in three such tests will determine whether the contents of a kiln or part of a kiln meet the average maximum abrasion loss specified; and the maximum variation between the percent abrasion losses of the three sets will be used to determine what portion of the bricks represented will be culled or rejected.

"**Sampling from PILES at the plant.** In general, samples selected from piles at the plant shall be as nearly as possible representative of the entire run of the bricks. Samples from piles shall be taken from as many different points corresponding to the length, breadth and depth of the pile as possible. In no case shall they be confined to the upper or outer few layers. Where controversy arises regarding the admissibility of certain types or portions of the lot, entire test samples may be selected from such types or portions having a characteristic appearance in common.

"**Sampling at Point of Delivery.** A representative sample should be taken from each carload received. Considerations covered under Sampling from Piles at the Plant apply equally to sampling from cars.

"**Shipping.** Samples shipped by freight or express to the laboratory shall be put up in packages containing 12 bricks each, packed in two rows separated by a partition for protection.

"**Condition of Bricks before Testing.** If bricks are damp, they shall be dried at a temperature of 89° C (100° F) before testing. No bricks shall be included in the test lot which would be rejected on the basis of cracks, chips, or other defects covered by the specification clauses for visual inspection."

The method adopted by the Am. Soc. Test. Mat. is described in Art. 9.

8. Methods of Testing Brick

Tests for Quality of Paving Brick usually made are now generally confined to one, the rattler test. Sometimes, however, a test is made for absorption and for the cross-breaking strength. Specifications also generally include clauses concerning the visual inspection of the brick in order to provide for especial uniformity in size and shape, and for homogeneity and freedom from flaws, nodules, voids, etc in internal composition.

The Absorption Test, when made, is usually carried out as follows: Five brick, which have been thru the rattler test, are thoroly dried and their weights recorded. They are then immersed in water for 48 hr, removed and dried superficially with blotting paper, and again weighed. The gain in weight is calculated and reported as the absorption, the percentage being based on the weight of the brick.

The Cross-Breaking or Transverse Test is as follows: The brick is supported upon two knife edges and a load is applied on the upper side midway between the supports by means of a third knife edge. The load is gradually

increased until rupture occurs. The result of the test is expressed in the ratio of the fraction $\frac{3\,P\,L}{2\,B\,D^2}$ called the modulus of rupture. In the fraction, P represents the breaking loads in pounds, L the distance between the supports, B the breadth of the specimen, and D the depth of the specimen, measured in inches. In making the test, a number of individual samples should be used so that a fair average of the lot may be obtained.

Rattler Test. For a description of the standard method of making the rattler test, see the Standard Specifications for Paving Brick of the Am. Soc. Test. Mat. given in Art. 9.

9. Specifications for Brick

The First Conference, 1917, State Highway Engineers and Chemists adopted the following specifications for paving brick.

All brick shall be of a size commercially known as vitrified block. They shall be thoroly annealed, tough and durable, regular in size and shape and evenly burned. When broken the bricks shall show a dense, stone-like body, free from lime, air pockets, cracks or marked laminations. Kiln marks shall not exceed .... of an inch, and the wearing surface shall show but slight kiln marks.

"Rattler Test. Representative samples of the brick shall meet the following requirements when subjected to the rattler test. Average loss by abrasion on one or more tests, not more than ....%. Maximum difference in percent loss by abrasion when more than one representative sample is tested, not more than ....%. A maximum of three tests will be used as a basis for rejection.

"Dimensions. The brick shall meet the following requirements: Length, ... inches to .... inches; width, ... inches to .... inches; depth, ... inches to .... inches.

"Variations among brick from a single plant shall not exceed the following limits: Variation in length, ... of an inch; variation in width, ... of an inch; variation in depth, ... of an inch.

"If the edges of the brick are rounded, the radius shall not exceed .... of an inch. Only brick with lugs on one side, raised not less than .... of an inch, nor more than .... of an inch, shall be used.

"Visual Inspection. The bricks shall be subjected to inspection subsequent to delivery at the place of use, prior to and during laying, in order to cull out and reject upon variations from the general and dimensions clauses and upon the following grounds: All bricks which are broken thru, or chipped in such manner that neither wearing surface remains substantially intact, or in such manner that the lower or bearing surface is reduced in area by more than one fifth. All bricks which are cracked to a depth greater than .... inch on any surface, or which are cracked on the wearing surface. All bricks which are so off-size or so misshaped, bent, twisted, or kiln-marked that they will not form a proper surface or align properly with other bricks. All bricks which are obviously too soft and too poorly vitrified to endure street wear."

The Am. Soc. Test. Mat. standard specifications for paving brick adopted in 1916, are as follows:

"The quality and acceptability of paving brick, in the absence of other special tests mutually agreed upon in advance by the seller on the one side and the buyer on the other side, shall be determined by the following procedure:

1. The Rattler Test, for the purpose of determining whether the material as a whole possesses to a sufficient degree strength, toughness and hardness.

2. Visual Inspection, for the purpose of determining whether the physical properties of the material as to dimensions, accuracy and uniformity of shape and color, are in general satisfactory, and for the purpose of culling out from the shipment individually imperfect or unsatisfactory brick.

"The acceptance of paving brick as satisfactorily meeting one of these tests, shall not be construed as in any way waiving the other.

"The Selection of Samples for Test. 1. PLACE OF SAMPLING. In general, where a

shipment of bricks involving a quantity of less than 100 000 is under consideration, the sampling may be done either at the brick factory prior to shipment, or on cars at their destination or on the street, when delivered ready for use. When the quantity under consideration exceeds 100 000 the sampling shall be done at the factory prior to shipment. Bricks accepted as the result of test prior to shipment, shall not be liable to subsequent rejection as a whole, but are subject to such culling as is provided for under Visual Inspection.

"2. METHOD OF SELECTING SAMPLES. In general, the buyer shall select his own samples from the material which the seller proposes to furnish. The seller shall have the right to be present during the selection of a sample. The sampler shall endeavor, to the best of his judgment, to select brick representing the average of the lot. No samples shall include bricks which would be rejected by visual inspection, except, that where controversy arises, whole tests may be selected to determine the admissibility of certain types or portions of the lot having a characteristic appearance in common. In cases, where prolonged controversy occurs between buyer and seller and samples selected by each party fail to show reasonable concurrence, then both parties shall unite in the selection of a disinterested person to select the samples, and both parties shall be bound by the results of samples thus selected.

"3. NUMBER OF SAMPLES PER LOT. In general, one sample of ten bricks shall be tested for every 10 000 bricks contained in the lot under consideration; but where the total quantity exceeds 100 000, the number of samples tested may be fewer than one per 10 000, provided, that they shall be distributed as uniformly as practicable over the entire lot.

"4. SHIPMENT OF SAMPLES. Samples which must be transported long distances by freight or express, shall be carefully put up in packages holding not more than twelve bricks each. When more than six bricks are shipped in one package, it shall be so arranged as to carry two parallel rows of bricks side by side, and these rows shall be separated by a partition. In event of some of the bricks being cracked or broken in transit, the sample shall be disqualified, if there are not remaining ten sound undamaged bricks.

"5. STORAGE AND CARE OF SAMPLES. Samples shall be carefully handled to avoid breakage or injury. They shall be kept in the dry so far as practicable. If wet, when received, or known to have been immersed or subjected to recent prolonged wetting, they shall be dried for at least 6 hr in a temperature of 38° C (100° F) before testing.

" The Construction of the Rattler. 6. GENERAL DESIGN. The machine shall be of good mechanical construction, self-contained, and shall conform to the following details of material and dimensions, and shall consist of barrel, frame, and driving mechanism as herein described.

"7. THE BARREL. The barrel of the machine shall be made up of the heads, head-liners, staves and stave-liners. The heads may be cast in one piece with the trunnions, which shall be 2½ in in diameter, and shall have a bearing 6 in in length, or they may be cast with heavy hubs, which shall be bored out for 2 7/16 in shafts, and shall be key-seated for two keys each ½ by ⅜ in and spaced 90° apart. The shaft shall be a snug fit and when keyed shall be entirely free from lost motion. The distance from the end of the shaft or trunnion to the inside face of the head shall be 15⅜ in in the head for the driving end of the rattler, and 11⅜ in for the other head, and the distance from the face of the hubs to the inside face of the heads shall be 5½ in. The heads shall be not less than ¾ in thick, nor more than ⅞ in thick. In outline, each head shall be a regular 14-sided polygon inscribed in a circle 28⅜ in in diameter. Each head shall be provided with flanges not less than ¾ in thick, and extending outward 2½ in from the inside face of the head to afford a means of fastening the staves. The surface of the flanges of the head shall be smooth and give a true and uniform bearing for the staves. To secure the desired true and uniform bearing the surfaces of the flanges of the head shall be either ground or machined. The flanges shall be slotted on the outer edge, so as to provide for two ¾ in bolts at each end of each stave, said slots to be 13/16 in wide and 2¾ in, center to center. Each slot shall be provided with a recess for the bolt head, which shall act to prevent the turning of the same. Between each two slots there shall be a brace ⅜ in thick, extending down the outward side of the head not less than 2 in. There shall be for each head a cast-iron headliner 1 in in thickness and conforming to the outline of the head, but inscribed in a circle 28⅛ in in diameter. This headliner shall be fastened to the head by seven ⅝-in cap-screws,

thru the head from the outside. Whenever these headliners become worn down ½ in below their initial surface level at any point of their surface, they shall be replaced with new ones. The metal of these headliners shall be hard machinery iron and should contain not less than 1% of combined carbon.

"The staves shall be made of 6-in medium-steel structural channels, 27¼ in long and weighing 15.5 lb per lin ft. The staves shall have two holes 13/16 in in diameter, drilled in each end, the center line of the holes being 1 in from the end and 1⅜ in either way from the longitudinal center line. The spaces between the staves shall be as uniform as practicable, but shall not exceed 5/16 in. The interior or flat side of each stave shall be protected by a liner ⅜ in thick by 5½ in wide by 19¾ in long. The liner shall consist of medium-steel plate, and shall be riveted to the channel by three ½-in rivets, one of which shall be on the center line both ways and the other two on the longitudinal center line and spaced 7 in from the center each way. The rivet holes shall be countersunk on the face of the liner and the rivets shall be driven hot and chipped off flush with the surface of the liners. These liners shall be inspected from time to time, and if found loose shall be at once re-riveted. Any test at the expiration of which a stave-liner is found detached from the stave or seriously out of position, shall be rejected. When a new rattler, in which a complete set of new staves is furnished, is first put into operation, it shall be charged with 400 lb of shot of the same sizes, and in the same proportions as provided in Par. 9, and shall then be run for 18 000 revolutions at the usual prescribed rate of speed. The shot shall then be removed and a standard shot charge inserted, after which the rattler may be charged with brick for a test. No stave shall be used for more than 70 consecutive tests without renewing its lining. Two of the 14 staves shall be removed and relined at a time in such a way that of each pair, one falls upon one side of the barrel and the other upon the opposite side, and also so that the staves changed shall be consecutive but not contiguous; for example, 1 and 8, 3 and 10, 5 and 12, 7 and 14, 2 and 9, 4 and 11, 6 and 13, etc, to the end that the interior of the barrel at all times shall present the same relative condition of repair. The changes in the staves should be made at the time when the shot charges are being corrected, and the record must show the number of charges run since the last pair of new lined staves was placed in position. The staves, when bolted to the heads, shall form a barrel 20 in long, inside measurement, between headliners. The liners of the staves shall be so placed as to drop between the headliners. The staves shall be bolted tightly to the heads by four ¾-in bolts, and each bolt shall be provided with a lock nut, and shall be inspected at not less frequent intervals than every fifth test and all nuts kept tight. A record shall be made after each inspection showing in what condition the bolts were found.

"8. THE FRAME AND DRIVING MECHANISM. The barrel shall be mounted on a cast-iron frame of sufficient strength and rigidity to support it without undue vibration. It shall rest on a rigid foundation with or without the interposition of wooden plates, and shall be fastened thereto by bolts at not less than four points. It shall be driven by gearing whose ratio of driver to driven is not less than one to four. The counter shaft, upon which the driving pinion is mounted, shall not be less than 1 15/16 in in diameter, with bearing not less than 6 in in length. If a belt drive is used the pulley shall not be less than 18 in in diameter and 6½ in in face. A belt at least 6 in in width properly adjusted, to avoid unnecessary slipping, should be used.

"9. THE ABRASIVE CHARGE. The abrasive charge shall consist of cast-iron spheres of two sizes. When new, the larger spheres shall be 3.75 in in diameter and shall weigh approximately 7.5 lb (3.40 kg) each. Ten spheres of this size shall be used. These shall be weighed separately after each ten tests, and if the weight of any large sphere falls to 7 lb (3.175 kg), it shall be discarded and a new one substituted; provided, however, that all of the large spheres shall not be discarded and substituted by new ones at any single time, and that so far as possible the large spheres shall compose a graduated series in various stages of wear. When new, the smaller spheres shall be 1.875 in in diameter and shall weigh approximately 0.95 lb (0.43 kg) each. In general, the number of small spheres in a charge shall not fall below 245 nor exceed 260. The collective weight of the large and small spheres shall be as nearly 300 lb as possible. No small sphere shall be retained in use after it has been worn down so, that it will pass a circular hole 1.75 in in diameter, drilled in an iron plate ¼ in in thickness, or weigh less than 0.75 lb (0.34 kg). Further, the small spheres shall be tested, by passing them over the above plate or by weighing, after every ten tests, and any which

pass thru or fall below the specified weight, shall be replaced by new spheres; provided, further, that all of the small spheres shall not be rejected and replaced by new ones at any one time, and that so far as possible the small spheres shall compose a graduated series in various stages of wear. At any time, that any sphere is found to be broken or defective, it shall at once be replaced. The iron composing these spheres shall have a chemical composition within the following limits: Combined carbon, not under 2.50%; graphitic carbon, not over 0.25%; silicon, not over 1.00%; manganese, not over 0.50%; phosphorus, not over 0.25%; sulphur not over 0.80%. For each new batch of spheres used, the chemical analysis shall be furnished by the maker or be obtained by the user, before introducing into the charge, and unless the analysis meets the above specifications, the batch of spheres shall be rejected.

"The Operation of the Test. 10. The Brick Charge. The number of bricks per test, shall be ten for all bricks of so-called block-size, whose dimensions fall between 8 and 9 in in length, 3 and 3¾ in in breadth, and 3¾ and 4¼ in in thickness.* No brick should be selected as part of a regular test, that would be rejected by any other requirements of the specifications under which the purchase is made.

"11. Speed and Duration of Revolution. The rattler shall be rotated at a uniform rate of not less than 29.5 nor more than 30.5 rev per min, and 1800 rev shall constitute the test. A counting machine shall be attached to the rattler for counting the revolutions. A margin, not to exceed 10 rev will be allowed for stopping. Only one start and stop per test is generally acceptable. If, from accidental causes, the rattler is stopped and started more than once during a test, and the loss exceeds the maximum permissible under the specifications, the test shall be disqualified and another made.

"12. The Scales. The scales must have a capacity of not less than 300 lb, and must be sensitive to 0.5 oz, and must be tested by a standard test weight at intervals of not less than every ten tests.

"13. The Results. The loss shall be calculated in percentage of the initial weight of the brick composing the charge. In weighing the rattled brick, any piece weighing less than 1 lb shall be rejected.

"14. The Records. A complete and continuous record shall be kept of the operation of all rattlers working under these specifications. This record shall contain the following data concerning each test made: (1) The name of the person, firm or corporation furnishing each sample tested. (2) The name of the maker of the brick represented in each sample tested. (3) The name of the street, or contract, which the sample represented. (4) The brands or marks upon the bricks by which they were identified. (5) The number of bricks furnished. (6) The date on which they were received for test. (7) The date on which they were tested. (8) The drying treatment given before testing, if any. (9) The length, breadth and thickness of the bricks. (10) The collective weight of the ten large spherical shot used in making the test at the time of their last standardization. (11) The number and collective weight of the small spherical shot used in making the test, at the time of their last standardization. (12) The total weight of the shot charge, after its last standardization. (13) Certificate of the operator that he examined the condition of the machine as to staves, liner, and any other parts affecting the barrel, and found them right at the beginning of the test. (14) Certificate of the operator of the number of charges tested since the last standardization of shot charge and last renewals of stave-liners. (15) The time of the beginning and ending of each test, and the number of revolutions made by the barrel during the test, as shown by the indicator. (16) Certificate of the operator as to number of stops and starts made in each test. (17) The initial collective weight of the ten bricks composing the charge and their collective weight after rattling. (18) The loss calculated in percentage of the initial weight and the calculation itself. (19) The number of broken bricks and remarks upon the portions which were included in the final weighing. (20) General remarks upon the test and any irregularities occurring in its execution. (21) The date upon which the test was made. (22) The location of the rattler and name of the owner, upon which the test was made. (23) The cer-
